IMAGINE a radio set without a vacuum tube, Milady's vanity dresser without its vermillion cosmetic, the bathroom chest without its reserve of mercury bichloride to guard against fleshy infection, the sick room without a thermometer, and your hunting ammunition unequipped with precussion caps. All of these utilize quicksilver, or mercury, in various quantities. Yet the average man or woman knows little of the origin of this liquid metal or of the methods through which it is extracted from sandstone and poured into flasks, ready for the many uses that man's scientific ingenuity has devised.

Still less do we know of the potential uses of this fluid-metal which touches the life of every man, woman, and child in that it brings freedom from agonizing pain, makes possible home comforts, kills crop-destroying insects, prevents the fouling of ship bottoms, and is used extensively to roughen the hairs of felt products.

Of the two and a quarter million pounds of mercury utilized in this country, only 10 percent enters into the manufacture of electrical apparatus. Yet here is a field that promises unprecedented demand for the metal and is responsible for the present revival in mercury mining. Few know that mercury is essential in the manufacture of neon lights which are now used for display sign purposes. The blue color produced by the neon sign is caused by the presence in the tube of metallic mercury which acts with the neon gas. The green color is produced by mercury without the aid of any other gas or chemical, but the glass tube is tinted.

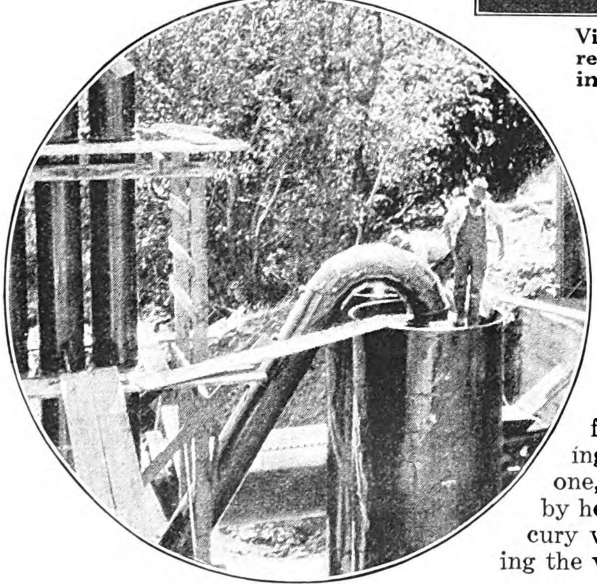
Of greater importance still is the promised use of mercury in power generation. Experiments conducted by the General Electric Company have demonstrated that mercury turbines have a heat efficiency of 85 percent, as compared to the 25 percent or lower heat efficiency of steam electric plants. If applied generally, anywhere from 11,000,000 to 17,000,000 pounds of mercury would be required to take care of the annual increase in generator capacity. This amount of mercury is more than the entire world now produces annually.

THE experimental installation consists of a mercury boiler and mercury-vapor driven turbine, as well as steam boiler and steam-driven turbine. After passing through the vapor-driven turbine, the mercury vapor is condensed. Steam is generated in this condenser by the heat delivered in the condensation of the exhaust mercury-vapor. The condensed mercury is then drained and returned to the mercury boiler. In this manner mercury can be utilized with very little loss.

Only 2.4 percent of the mercury used in this country enters into the manufacture of scientific instruments, such as thermometers and barometers. By far the largest amount—to be exact 32.2 percent—is required by the drug and chemical industries. The largest single use is for fulminate, an explosive, and next in order, for vermillion and oxide. Only a little over 3 percent is used for gold and silver milling, although during the bonanza days in gold mining very large quantities of mercury were needed to amalgamate gold and silver from the metallic ores. In the heyday of gold mining, California, which is our largest mercury producing state, enjoyed a record annual production amounting to 4,000,000 dollars, but now the production has fallen to less than a million. For many years the domestic mercury industry was practically at a standstill, only to be revived recently by increasing demands in industry.

A NUMBER of the old mercury mines in California, which have been idle for years, are now thriving with renewed activity. The Oat Hill Mine, which the writer visited recently, again began to produce the metal from low-grade ore only a few months ago, after it had been abandoned for four or five years. Low prices, substitution of cyanide for gold and silver extraction, and the competition of foreign mines, were responsible for almost a dead stop in domestic production. No other metal has suffered as much from the inroads of substitution. It was formerly used in large quantities to "silver" mirrors, but is now almost entirely replaced by a silver nitrate process. Even as a fulminate, other substitutes have been found, in which lead and silver form the principal products. Now that mercury has been demonstrated as an efficient power generation agent, research has revealed a suitable substitute for it in the form of diphenyl oxide, which is a by-product in the manufacture of carbon tetrachloride and chloroform.

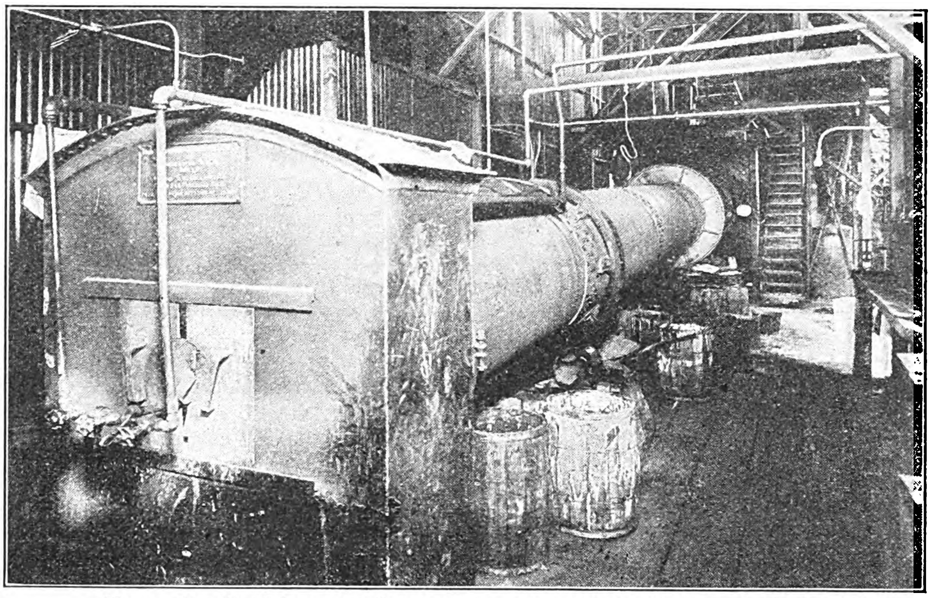
YET, despite its age-long battle with substitutes, mercury has persisted as a separate mining industry since the Phoenicians first began to work the famous Almaden Mine 27 centuries ago. Today this mine, operated by the Spanish government, produces more than one third of the world's supply of mercury, and shows no signs of depletion. Last year this mine produced half of the world's supply. Italy was the next largest producer, and the United States came third in the production of this metal.



From the cyclone tank, on which stands a man, mercury vapors are piped into condensers

The principal mercury mines in California are located without exception in the coast range, where the ore has been lifted toward the surface by volcanic action. The mines are usually located in the vicinity of hot springs. Due to the surface operations, mercury mining in California has not been marked by the hazards of fissure digging in the Almaden deposits, where men have gone to depths of several thousand feet. Due to the greater heat at 2000 and 3000 feet below the surface, mercury has been known to run down the stope walls as so much liquid, thereby subjecting the miners to the danger of mercurial poisoning. Surface mining, confined largely to depths of several hundred feet, have tended to reduce hazards, and the danger of poisoning by contact with vapor has been largely eliminated by the use of modern furnace and condensing equipment to be found in the California mines.

At the Oat Hill Mine, tunnels are bored into the hillside and the ore removed to the surface on a narrow-gage roadway. The ore is a sandstone dotted with red, and is known technically as cinnabar. This heavy, vermillion-colored mineral is composed largely of mercury and a smaller amount of sulfur. The process of extracting the mercury is a simple one, the metal being distilled by heating the ore until the mercury vaporizes and then condensing the vapor into a liquid. This is followed by a purification process to get rid of the sulfur, as well as of carbon monoxide gas and other dangerous fumes. The final process is to "hoe" the mercury from its slimy blanket of soot. The refining process is accomplished entirely at the mine, and takes place within a few minutes after delivery of the crushed ore to the furnace.



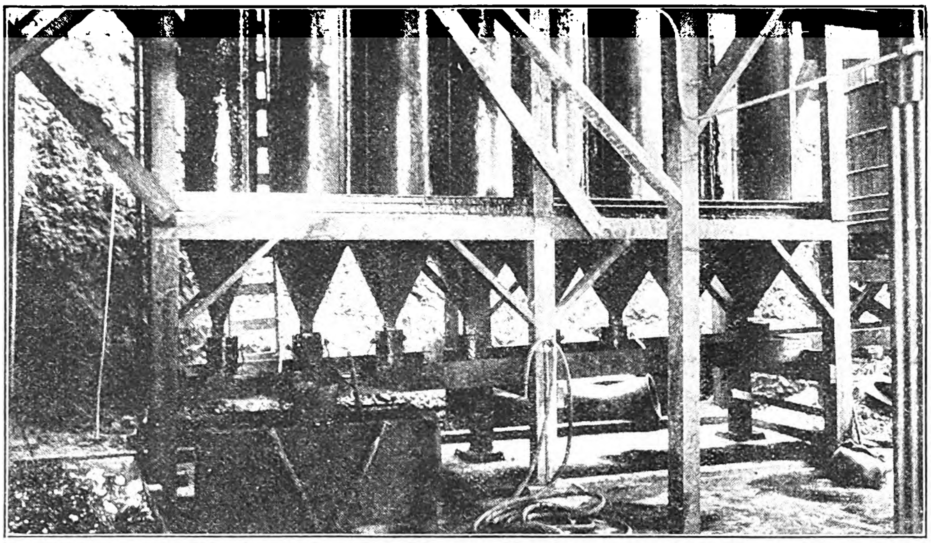
View of a Gould rotary furnace, a type now used extensively for the refining of mercury. Its rotating action helps volatilize the mercury in the ore. Its construction and operation are described below

In mercury mining, a tunnel is driven to as great a depth as 750 feet. There are innumerable tunnels to be found in the vicinity of the Oat Hill Mine, and it is estimated that in the 60 years that this mine has been producing the metal no less than 24 miles of tunnel have been driven. During that time the Oat Hill Mine has produced some 19,000,000 dollars worth of the widely used liquid metal.

From the mouth of the tunnel, the ore rock is conveyed to the gravity sorting bin by a three-ton motor truck. After a perilous mile and a half trip over a one-way mountain road, the truck is backed up onto a loading platform, from which the rock is catapulted several hundred feet to the storage bin below. Yet this truckload of rock will produce only 12 or 18 pounds of mercury, figured at from four to six pounds of the metal to the ton of ore. At present prices—and they are high—a pound will bring less than two dollars, or more than double the production cost. The present price is treble the average price of mercury in the United States during the past 40 years, while production cost has been reduced by utilizing more efficient production methods.

BEFORE the ore is fed to the furnace, it must be crushed and sorted. An automatic feeder introduces the ore particles into the rotary furnace at the rate of 10 pounds every minute. The feeder can be adjusted to feed the ore in various quantities and in different sizes, depending on both the type of ore and the roasting conditions. The "feed" then has to go through the 60-foot rotary furnace, which slowly revolves in order to facilitate volatilization of the mercury from the ore. At the point that the ore enters the furnace a temperature of 1800 degrees, Fahrenheit, is maintained, this being decreased to 450 degrees at the mouth of the furnace.

The rotary furnace turns three fourths of a revolution per minute and inclines at three fourths of an inch to the foot. At the same time that the vapor rises from the ore, the revolving action raises the dust as the rock proceeds downward. A powerful fan in



Mercury condensing system. The vapor travels through these condensing tanks and is deposited as a sort of sludge or slime in the hoppers below

the dust chamber at the head of the furnace sucks the vapor and dust into two cyclone tanks, in which the dust settles and the mercury vapor is made to proceed to the series of 12 condensers. The first cyclone tank is smallest and collects most of the dust. As the dust and vapor enter the cyclone they are driven by centrifugal action from the center to the metallic walls, with the result that the dust, being heavier, will settle, while the vapor, combined with smaller quantities of dust, will undergo further separation in the second, and larger cyclone. The light gaseous vapor naturally rises to the top of the tank directly into pipes which lead to the series of condensers.

The condensers are 16 feet long and 19 inches in diameter. At the bottom of each condenser unit is a cone-shaped outlet. The hot gas enters directly into this lower cone, where it deposits some of its dust, and then travels through a circular pipe to the height of the condenser. The vapor condenses into the familiar liquid against the cool walls, and this liquid metal drops to the cone-shaped hopper, or outlet.

A CERTAIN amount of the condensed mercury will adhere to the wall and can be removed into the hopper below by unscrewing the clean-out hole at the top of the condenser and flushing the walls with water. Even at this stage the mercury can be removed from the hopper in the first condenser in the form of a whitish slime from which the quicksilver must be hoed out.

A certain proportion of the mercury vapor will fail to condense in the first condenser, and will therefore circulate through the other condensers in the series. Experience has shown that most of the mercury will be deposited in the second and third hoppers. The complete series of 12 condensers is needed in order to catch every minute globule of mercury before the sulfur and other gases are afforded an escape to the purifying tanks.

The three purifying tanks are connected by a small pipe. Thus by a process of compression, when the gases enter the pipes, and by expansion during the journey in the tanks, considerable heat is generated, propelling the sulfur and carbon monoxide gases to the stack, from which they are vented into the air.

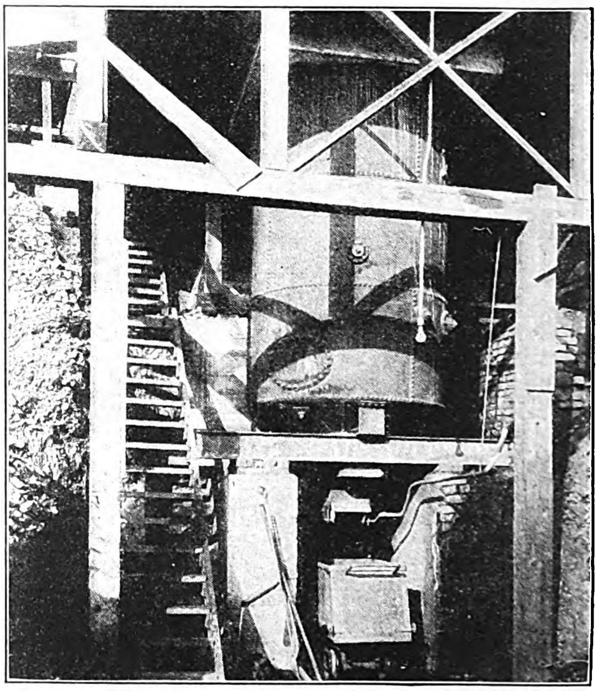
The whitish slime gathered from the hoppers is dumped on a round table. A man with a hoe separates small quantities of the slime, and as he does so, small streams of mercury globules are seen to flow to the opening on the lower end of the table and into a metallic flask which normally holds 76 pounds of mercury. Properly sealed, this flask is ready for the market.

The hoeing process is a survival of ancient times. The minute globules of mercury present in the slime are practically invisible to the naked eye. The action of the hoe loosens the slime in small quantities, making it possible for the small globules to seek each other out, much as drops of water coalesce into a small stream. It is the simplest, yet most interesting process of mercury refining—and the most hazardous.

The hoeing action must be slow; otherwise it will raise little eddies of dust, which if swallowed, even in minute particles, is sure to cause mercurial poisoning. The first symptom of the poisoning is loosening of the teeth, followed by disruption of the digestive system. If the poisoning is not arrested, the operator will suffer an attack of nerves. Leaky pipes in the roasting and condensing system are now the chief cause of poisoning. In the ancient Almaden mines there were so many cases of poisoning that the occupation was considered too dangerous for a free man; therefore convict labor was extensively employed.

H. W. GOULD, a San Francisco mining engineer, recently perfected a mechanical hoeing device which it is expected will eliminate the inefficiency and the hazards of hand hoeing. This device is equipped with mechanical rabble arms to separate the slime and afford free movement for the mercury globules. Mr. Gould is also the inventor of the rotary furnace which is now used extensively in American mercury mines, and is gradually replacing the older methods employed in foreign operations. It is especially adapted for low-grade ores which formerly could not be worked at a profit. At the Oat Hill Mine the rotary converts 80 tons of ore every 24 hours. This ore has less than 0.25 percent of quicksilver. At the Spanish mines the ore has about 8 percent of mercury and can, therefore, be mined economically with the older methods of refining. Although these mines have been worked since 800 B.C., richer ore is now being extracted from great depths.

Paul M. Tyler, of the Federal Bureau of Mines, says that "in many lines, substitutes for mercury are employed; but in other lines there is a constant ebb and flow as consumers experiment with first one and then another, only to return to mercury. . . . To have faith in the future of modern industry is to have confidence in the future of mercury."



Waste ore from the furnace is deposited in a retort and is removed in carts to the rock dump

PROHIBITION and the Physiological Effects of Alcohol

By H. H. MITCHELL
Professor of Animal Nutrition, College of Agriculture, University of Illinois

THE most acute political question of this generation is at the present time being debated largely on the basis of uncertain statistics, and interpretations of them biased by inflexible opinions in regard to moral standards or personal liberty. It should be obvious to those who approach the question of the advisability of national prohibition with an open mind that reliable statistics on the success of prohibition enforcement are not at hand. The interpretation of trends in penal, industrial, and other social statistics that are at hand, in terms of assumed trends in the consumption of alcoholic liquors nevertheless is the stock in trade of the political prohibitionist and the political anti-prohibitionist. After reading the propaganda put out by both sides of the argument, one can agree wholeheartedly with Josh Billings, when he said that it is better not to know so much than to know so many things that aren't so.

THE enactment of legislation aiming at the restriction of the sale of alcoholic liquors can be justified only on the basis of the harmful effects of alcohol on the human body and on human behavior. The extent to which the consumption of liquor should be restricted depends upon how harmful alcohol is and in what dilution its effects become inappreciable. Few would doubt the wisdom of governmental restriction of the sale of the alkaloidal narcotics. The question with respect to alcohol may and should be argued on the same basis, though the answer need not be the same because there are certain compensations in the use of alcoholic beverages that do not pertain to the use of the more powerful narcotic drugs. Without minimizing the importance of the purely practical problems of the probable effectiveness of the machinery for the enforcement of liquor legislation and of the expense involved, it appears to be no exaggeration to say that the purpose and the form of such legislation should be determined largely on the basis of scientific data in regard to the physiological and psychological effects of alcohol.

How does the human body dispose of the alcohol contained in consumed liquor? Requiring no digestion and being readily soluble in water and readily diffusible, it is rapidly absorbed from the digestive tract. In fact, absorption may start in the stomach, from which practically no absorption of the ordinary food nutrients occurs. The absorbed alcohol is taken up by the blood stream and carried to all the tissues of the body. Its ready diffusibility in aqueous media accounts for its penetration into all organs, and after a time it may be present in the brain, liver, kidneys, spleen, heart, and lungs in concentrations approximating that in the blood. Even after moderate doses of alcohol, it may be detected in the expired air, in the urine, and, with nursing women, in the milk secreted.

OF heated articles about prohibition there already have been no end. It may be stated with fair confidence that 90 percent of the general public is thoroughly and heartily sick and tired of them. It is getting so that many people, when they sense the approach, say at dinner, of an oral tilt about this threadbare subject, let out a groan of despair and slide into oblivion under the table. At least they feel like doing so.

Is it not possible that this widespread reaction to the prohibition question is due partly to the fact that one so seldom reads an article or listens to an argument on prohibition that seems really calm and unbiased? But we publish Professor Mitchell's article because we believe it is just that—calm and unbiased. If as a result of its publication we receive a half bushel of letters saying it leans toward the "Demon Rum," and another half bushel saying it leans equally in the opposite direction, our own belief — that it does not lean at all —will be flattered.—*The Editor.*

But the body does not dispose of ingested alcohol to any great extent by excretion from lungs or kidneys. Only five percent or less is gotten rid of in this way. Alcohol is combustible in the body, and is very readily burned to carbonic acid and water, as are sugars and fats. The energy thus liberated may be used by the body in the same way and for much the same purposes as the energy produced from the burning of sugars and fats. But it has not been shown that alcohol can be transformed to sugars or fats and stored in the body.

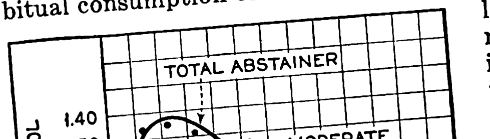
Hence, after a drink of alcoholic liquor the concentration of alcohol in the blood and tissues will rapidly rise to a maximum in the course of one to two hours, depending on the concentration in the liquor consumed, but then it will gradually decrease until after a variable period of time the body will be alcohol-free or practically so. It has been estimated by Mellanby in England, that an average man can burn only from 7 to 10 cubic centimeters of alcohol per hour, so that the time required for the body to rid itself of this substance will be directly dependent upon the amount consumed. A moderate dosage of alcohol, for example, 30 cubic centimeters or approximately one fluid ounce, contained in a pint of fairly heavy beer, would be disposed of in three to four hours or so, but an intoxicating dose may take from 10 to 20 hours for complete combustion.

THE physiological and psychological effects of alcohol have been shown to vary in intensity with the concentration of alcohol in the blood. When the blood contains no more than 0.1 percent of alcohol there are no obvious signs of intoxication. A concentration of .15 percent of alcohol, following the consumption of about 100 cubic centimeters of alcohol (4 pints of beer or 7 to 8 ounces of whisky) on an empty stomach, is associated with a moderate state of intoxication. With increasing consumption of alcohol the maximum concentration in the blood will increase to 0.5 percent, which may be associated with stupor. When a concentration of 0.6 percent is reached, life itself is endangered. Some recent German investigations, in which more recent methods for the analysis of blood for alcohol were used, would indicate that these values may all be low, but the fact remains that alcoholic effects are correlated with alcohol concentrations in the blood, and that the lethal concentration is uncomfortably close to that associated with alcoholic stupor.

It is well known that the effects of a given dose of alcohol depend upon its dilution as consumed. More alcohol may be consumed in dilute solution than in concentrated solution in proeing a given physiological effect, ecause the time of absorption is ex- nded. In agreement with this fact, has been found that the more con- ntrated the solution of alcohol con- med, the greater the blood concen- ation attained and the quicker the aximum concentration is reached. ernon has shown, in illustration of e same relation, that amounts of lcohol may be consumed in small ourly doses without physiological ffect, which in the aggregate would roduce intoxication.

It is also well-known that the consumption of alcoholic liquor during or immediately after a meal produces a much smaller psychic effect than consumption on an empty stomach, for example, three hours or more after a meal. A number of investigations agree in showing that the alcoholic content of the blood is less if a given dose of liquor is drunk immediately after a meal than three or more hours after. The consumed alcohol mixes with the food in the stomach and is diluted by it, so that the rate of absorption in considerably less. Fatty foods are particularly effective in this respect.

Again, it is a matter of common experience that a person not accustomed to alcoholic liquor is more readily affected by it than is a habitual user. And again the blood picture offers an explanation. Thus, Schweisheimer showed that if total abstainers, moderate drinkers, and heavy drinkers imbibe the same quantity of alcohol under the same conditions of dilution and time after the last meal, the resulting concentration of alcohol in the blood is highest for the abstainer and lowest for the habitual heavy drinker. Furthermore, the observed differences were considerable. Possibly the habitual consumption of alcoholic liquors impairs the absorptive powers of the digestive apparatus, or possibly some obscure protective mechanism is developed.



From W. Schweisheimer in Deutsches Archiv fur Klinische Medizin 1912-13

The effect of habituation to alcohol on the concentration of alcohol in the blood after the ingestion of 1.57 cc. per kilogram of body weight (corresponding to about four ounces for a 150-pound man)

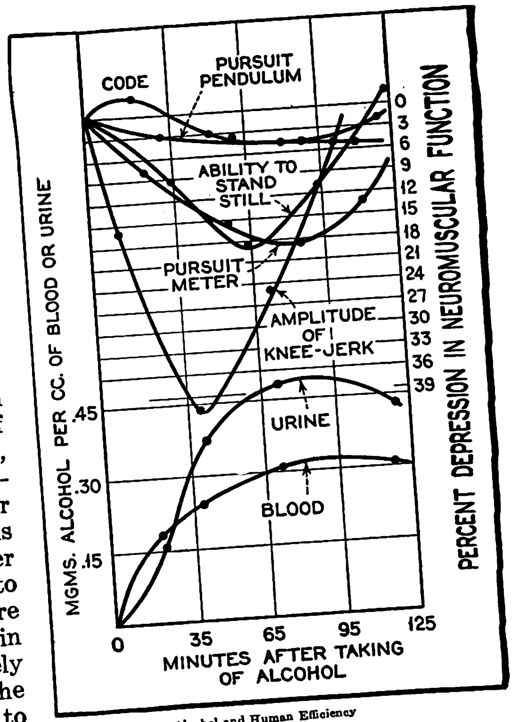
It is true that alcohol is a food in the sense that it is easily oxidized in the body, but unlike the ordinary nutrients it is toxic when it attains even a moderate concentration in the blood and tissues. Also unlike ordinary nutrients, the body has no effective means of regulating its concentration in the blood. When a healthy normal person consumes sugar or starch, even in large amounts, the concentration of sugar in the blood will rise rapidly, but when the rate of absorption exceeds the rate of oxidation and sugar begins to accumulate in the blood, it is withdrawn from the blood by the liver and the muscles, converted into glycogen or fat and stored for future use. The concentration of sugar in the blood will for this reason rarely exceed 0.15 percent. But in the diabetic, who has lost the power to oxidize sugar or to store it in any considerable amount, the consumption of sugars and starches will increase the concentration of sugar in the blood to 0.30 percent or more, and the accumulated sugar clogs the physiological machinery, so that diabetic coma and even death may result.

THERE is thus a similarity between the effects of sugars and starches on persons afflicted with diabetes and the effect of alcohol on normal persons. The diabetic can dispose of absorbed sugar only (or mainly) by way of the kidneys; the normal individual can dispose of alcohol only (or mainly) by way of oxidation, but in both cases the mechanism of disposal is effective only to a certain limit of consumption, beyond which increasingly disastrous effects will ensue, even to the point of death. Thus, regulation of the composition of the blood in neither case is a physiological one, but is largely a matter of voluntary control. However, the diabetic is aware of his condition and of his own peculiar dietetic dangers, and trains himself under medical guidance to limit his consumption of dangerous foods to his own particular tolerance for them. Can the same be said of the habitual drinker?

The outward symptoms of alcoholism are familiar to all, but it is of interest to quote a precise description of them as analyzed by a noted English physiologist, the late Professor E. H. Starling:

"The effects of acute alcoholic poisoning may be described as a continuous and progressive impairment and abolition of the functions of the brain, starting at the highest evolutionary level and progressing downwards. The stage in which there is lessened self-criticism, greater freedom of utterance, and diminished self-control is succeeded by a phase in which there is interference with the social habits of the individual, while the co-ordination of muscular movements becomes more and more imperfect. This gives place to a condition of stupor or drunken sleep in which the individual may persist for many hours until the greater part of the alcohol has been oxidized in the tissues and its concentration sinks once more below the poisonous level. In the drunken sleep the noisy, labored breathing often shows the beginning of interference with the innervation of the respiratory muscles, and if the dose has been sufficiently large this may lead to death from paralysis of respiration. . . . In some cases the result may be a profound shock from the direct irritant effects of the strong alcohol on the stomach, and heart failure may be associated with the gradual failure of respiration."

Popular opinion throughout the



Data from Miles, Alcohol and Human Efficiency

Effect of a small dose (27.5 grams—about an ounce) of alcohol in dilute solution (2.75 percent) on selected neuromuscular responses and the alcohol content of blood and urine. The curves represent averages from eight subjects. The neuromuscular responses may be described briefly as follows: Efficiency of eye-hand co-ordination was tested by the "pursuit pendulum," with which the subject catches in a small cup as much as possible of a stream of water flowing from the lower end of a moving hollow pendulum. Continuous eye-hand co-ordination was measured by the pursuit meter, an electrical instrument of some complexity—the subject, by manipulating a rheostat, endeavors constantly to keep a wattmeter needle on the zero-mark in spite of fluctuations in the electric circuit automatically induced by a disturbing device which remains beyond his control

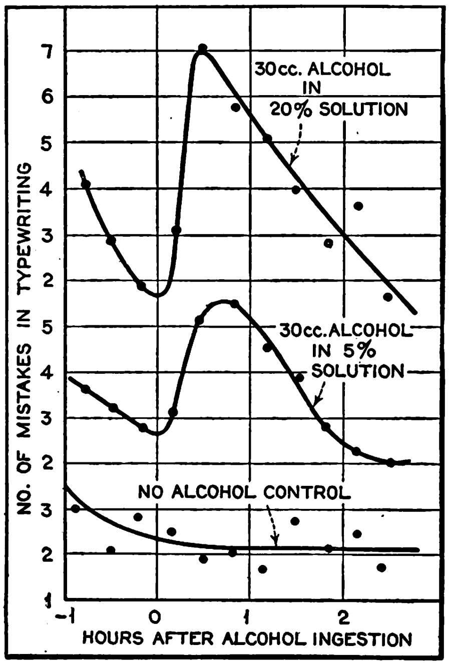
civilized world favors some type of governmental action to decrease the likelihood of alcoholic intoxication, a condition which is disgusting to see and degrading to its victims. The pleasing effects of alcohol are, however, realized long before this condition is reached. The temperate use of alcoholic liquors induces a condition that has been sympathetically described, also by Starling. Picturing a man who is attending a feast of which alcoholic drinks form an integral part, Starling says:

"A man may go to such a dinner full of the cares and work of the day, with little or no interest in those he has to meet, whose occupations may be very diverse from his own, nervous of making any remarks to his neighbors for fear of making himself ridiculous or saying something in which they are not interested. After the first glass of champagne we notice the conversation, instead of being spasmodic and forced, becomes general and free; the self-consciousness and preoccupation of each man with his own affairs become lessened. He is more receptive of the moods and interests of his companions. His emotional responses are more readily aroused; the solemn man unbends, the critical becomes charitable and sympathetic, the silent man more loquacious. Each man thus not only reveals himself more to his fellows, but is more ready to appreciate the merits and conversation of those around him. In a word, the use of alcohol in moderation promotes good fellowship. With this greater freedom of interchange of ideas there is less restraint of gesture; facial expressions become more animated; ideas in every man seem to flow more freely and speech becomes more ready."

EVEN though at such a feast, a second or a third glass of champagne may change the conversation from witty repartee to boresome anecdotes and maudlin expansiveness, there is surely no occasion for the interference of organized society. But when the party breaks up and its members enter their various automobiles for the trip home, possibly through congested traffic, have their psychological reactions and their muscular co-ordinations been so adversely affected that as motorists they are to some degree menaces to public safety? Or if it is a midday meal, and they have an afternoon of work in office, shop, or factory before them, have their physical and mental efficiencies been impaired by this convivial feast?

Unfortunately these questions must be answered in the affirmative. Many physiological laboratories throughout the world, particularly the Nutrition Laboratory of the Carnegie Institution at Boston, have demonstrated beyond reasonable doubt that the consumption of even moderate amounts of alcohol, in dilutions of 10 percent to as low as 2.75 percent, depresses the function of the nervous system generally and in many respects to an appreciable and even a considerable extent. It is true that much of this work relates to drinking between meals rather than at meals, but the results are applicable, if in less degree, to the case in point. Furthermore, it may be supposed that wherever the desirable psychic effects of alcohol are observed, the depressant effects are invariable accompaniments, since both must result from an increased concentration of alcohol in blood and tissues.

If a participant of Starling's feast attempts to stand perfectly still, the swaying of his body may be greater by almost one fourth than it was before the feast; if he attempts to follow with his eye a quickly moving object, or if he attempts to adjust some instrument with his hand according to the guidance of his eye, his performance will be definitely subnormal. His visual acuity has been decreased and the amplitude of his knee jerk (patellar reflex) has been depressed. If he is a skilled typist, his speed in typewriting will be to some extent lowered and the number of errors perpetrated will be greatly increased. In the case of a woman, her speed in threading needles will be much less than normal. In these and many other ways, it has been shown that alcohol in very moderate doses is a depressant, though the imbiber will have the subjective impression that he is performing faster and better than normal. The more skilled the task, the greater is the depression in efficiency.



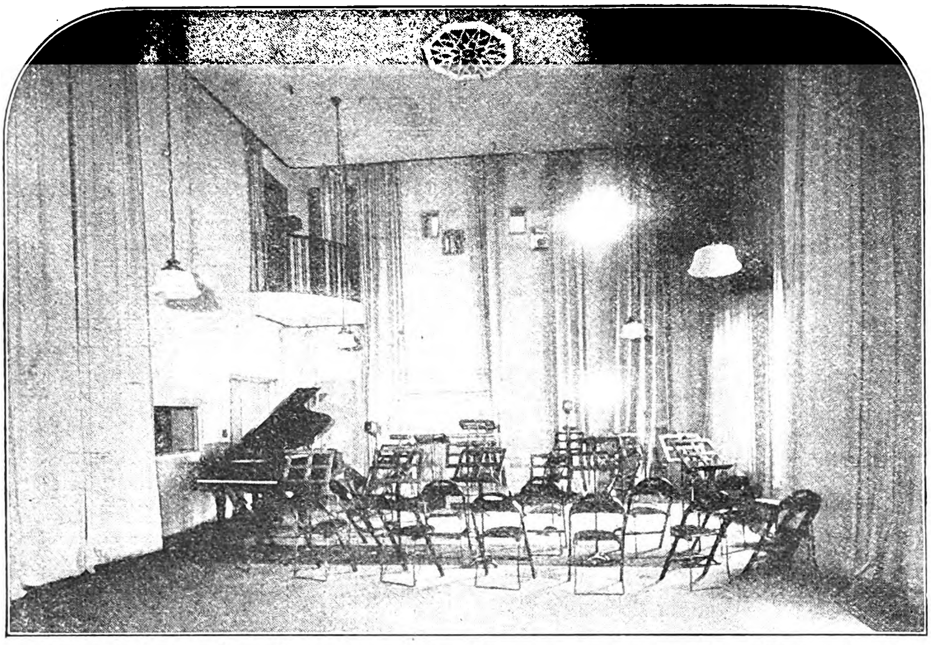
From Report No. 34 Medical Research Committee (Great Britain)

The effect of 30 cc. (about an ounce) of alcohol, taken in dilutions of 5 and 20 percent, on the accuracy of typing a memorized short passage, which required a maximum of two minutes to type

It is very doubtful whether alcohol ever exerts even a small initial stimulating effect on the nervous system, as has been maintained in the past. The change in point of view has resulted from improved methods of study. It is now recognized that many physiological processes are normally kept slowed down by higher controlling centers. When these centers are depressed by alcohol, or ether, or chloroform, the lower mechanisms are released with some of the signs of stimulation, such as an increased pulse, or a flushing of the surface capillaries with an increased flow of blood. The effect resembles that following releasing the brakes of an automobile, as contrasted with increasing the pressure on the accelerator. A British scientific board has summed up the evidence in the statement that "the direct effect of alcohol upon the nervous system is, in all stages and upon all parts of the system, to depress or suspend its functions; that it is, in short, from first to last, a narcotic drug."

THESE scientific findings render superfluous any statistical inquiry of the effects of alcohol consumption on industrial efficiency. A depression of efficiency of some degree is almost an inevitable consequence of even the moderate use of alcohol. The effect upon criminal tendencies can not be so clearly deduced, but the common association of liquor with crime, even before the prohibition regime, must be something more than an accidental one. In so far as the criminal is a psychopath, with an inherited tendency to mental and nervous instability, he is, according to Starling, an especially susceptible victim of alcoholic poisoning.

The facts discussed in this article are not presented as the sole evidence upon which the wisdom of prohibition should be decided. But it may be contended that they should form an important part of that evidence. The basis of discussion of this question should be shifted from the grounds of morality, social reform, and personal liberty, which possess merely a sentimental appeal, to the sounder basis of the control of the sale of alcohol as a narcotic drug. Its potency is much less than that of other drugs long known to be narcotics, but the much more prevalent use of alcohol in much greater amounts will of necessity occasion more misery, ill-health, and inefficiency. However, the use of alcoholic liquors by a large proportion of the population is a striking testimonial to its contribution to the pleasures of life and to conviviality. The solution of the question of liquor control should possibly be a compromise between these opposing arguments.



One of the studios where recorded radio programs are made. Two microphones are visible, one on each side of the window in the background

Recorded Radio Programs

By A. J. KENDRICK

President, Sound Studios of New York, Inc.

IN England the broadcast program is paid for by the public, which is taxed, the money collected being turned over to the radio stations to defray the expenses of broadcasting. The sponsored program does not exist.

In this country, however, business interests, awake to the good-will that may be created for their products and services via the air, pay the stations for the privilege of broadcasting programs. The sponsor also pays for the programs, which entertain the radio public and create good-will for the sponsor. This American system of broadcasting, which makes of radio a business asset, has also introduced a new industry to take the place of that older one which has found the going hard in the face of radio competition. The old industry to which we refer is that of making phonograph records. The new one is the recording of broadcast programs.

It might appear that these two industries are quite alike. They are—in outward respects. The new one has grown from the older. But the new one has progressed to that point where a person familiar only with the old method of phonographic recording would be lost in the new science of recording radio programs. On the other hand, those who would do fine work in the new industry should have at their command experience in the phonograph field, should have grown up hand in hand with recording, from its primitive days to the present time.

It was with the basic idea of creating an organization based on quality that Sound Studios of New York was founded. With Gustave Haenschen and Frank Black, well known in the phonograph and radio worlds, as Vice Presidents and directors of music, we were assured of artistic programs that would please the audience and gain good-will for the sponsors. With C. Lauda, Jr., an authority on acoustics, as Chief Engineer, we were well taken care of on the technical end, especially since he immediately surrounded himself with experts to handle every phase of recording.

THEN we procured studios and equipment of the latest type. Desiring to have full responsibility over every step in the making of recordings, we acquired turntables and recorders, microphones and studios, galvano baths and presses, shaving machines and buffing machines—every item for making disks. With a most complete plant and equipment, with a musical library as fine as any anywhere, with experts along every step of the way from business men and executives, through musical directors, talent, technicians, and workers, we felt ready to proceed.

We formulated ideals and we have stuck to them, without trying to discredit other firms or individuals who are doing a good job. We will rent our studios and equipment and the services of our technicians for recording programs not prepared by us. But we insist that they be of high quality, for we cannot afford to have poor programs recorded in our plant. Nor do we allow the release of programs prepared and recorded by us to stations not properly equipped to broadcast them. The results of these ideals, equipment, and personnel have been the recognition on the part of sponsors and stations that recorded programs have a definite place in the radio field if done properly, and the building of a clientele of the foremost sponsors.

RECENTLY, the Western Electric Company, having developed recording and broadcasting apparatus to a point hitherto unreached, equipped a number of broadcasting stations for operation from disk recordings. Others are being equipped every day. Looking about for a recording company whose work and personnel merited the installation of recording apparatus, Sound Studios of New York was chosen as the recipient of the first Western Electric license for the recording of broadcast programs. An entirely new set of equipment is now being installed in our studios, covering every feature of recording.

Recording broadcast programs involves a combination of artistry and engineering. The artistry lies in the preparation of the program, which should reflect the character, mood, tempo, and atmosphere of the sponsor and his product, appeal to the audience whom he wishes to address, and please that audience, making the listener desire to purchase the sponsored product.

The program having been prepared, the musicians and vocalists rehearsed, and the program given over the network, let us suppose that the sponsor wishes to get the full benefit of this fine program. He desires to use it for "spot" broadcasting from independent stations.

The recording studio is prepared. This room looks very much like any fine broadcasting studio, with soundproof walls and ceiling, ventilator to keep the room at constant temperature, control room looking upon the studio through a glass window in the wall, microphones, and so forth. In addition, there are the turntables, both for the small 10- or 12-inch records which revolve at 78 revolutions per minute and play about $4^{1}/_{2}$ minutes, and for the large 16-inch disks which revolve at $33^{1}/_{3}$ revolutions per minute and play for 10 minutes.

These turntables are powered by synchronous motors, which maintain a constant speed in spite of voltage fluctuations or other factors. The turntables are equipped with faders, by means of which one turntable may be faded off and another faded on, causing no break in the performance when it is desired to play two disks without interruption.

LET us suppose that a program is to be recorded on a 16-inch disk. Disks for broadcast recording, by the way, play from the center toward the rim, the reverse order of the usual commercial records. They are of the lateral cut type, the grooves being of constant depth and the stylus cutting the walls of the grooves; as contrasted to the "hill and dale" type, the name of which describes its principle. The wax—which is really made of soap material—is placed on the turntable, the motor set and the microphones properly placed in the recording studio. Then the program is begun. The man in the control room lowers or raises the volume of each microphone independently. So it is that the soloist is heard above the orchestra even though in the recording studio she cannot be heard above the roar of the drums and the horns as she barely whispers into the microphone which is before her. Sometimes as many as four "mikes" are used at once.

The performance over, the wax, now referred to as having been "cut," is placed in the galvano bath. Swishing back and forth on the end of a long rod in the bath, the cut side of the wax is electroplated, after which the resultant copper "master" is stripped off. This, of course, is a negative of the wax, its marks being raised above the surface whereas in the wax they were indented. The "master" is then taken to the pressing room where two test pressings are made from it. The test pressings are composed of a combination earth-shellac material, identical with the material of the final pressings. This substance is heated, then placed in the press with the "master" and, under enormous pressure and heat, baked. The test pressings are then played for the approval of all the parties concerned. The musical director looks for faults, the sponsor listens closely, the technicians try to find something amiss. If everything is perfect, performance and recording, the technicians, musical director, and sponsor O.K. the pressing. Perchance a certain selection was not as good as it might be. It is performed over again and recorded. Then the first record is played again and recorded on a clean wax, the re-recorded selection being "dubbed" in at the proper time, in much the manner as a movie strip is inserted in the final film. Another "master" is made, and test pressings approved.

Were the final disks pressed from the "master," there would be no impression of the performance should the "master" be injured in the pressing, for the wax has already been shaved for future use. So the "master" is in turn electroplated and the resultant "mother" taken from it. The "master" is then filed away for safe keeping or use for subsequent orders for more pressings of that performance. But the "mother" has its lines indented. It cannot be used to press the final disks. So it too is plated and the "stamper" coming therefrom used to make the final pressings, which are then ready for the broadcasting stations, where they are transmitted by the use of apparatus similar to that on which they were recorded. In this manner is a radio broadcast program recorded.

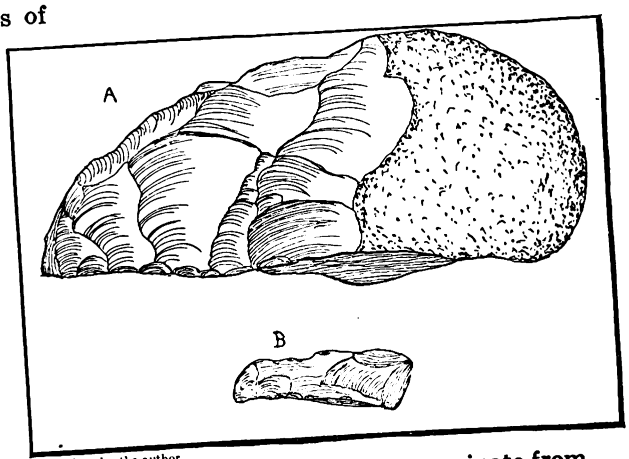
Making test pressings. The earth-shellac compound is being heated at the right to the consistency of dough. *Left:* One of the disk-baking presses

The uses of the recorded program are many and varied. It enables the independent station far from sources of entertainment talent to broadcast programs equal in quality to the finest network offerings, thereby enhancing its reputation and increasing its value to the sponsor. It enables the sponsor to reach his country-wide audience at the same hour despite time differences between the east and the west. It permits the use of radio by sponsors unable to book time on the networks; and for those already using the chain, makes possible the fullest use of their fine network programs. The cost of recording being divided between all the performances given by the disks, the individual programs are low in price, without loss of quality. The recorded program permits of editing, taking the finest portions of several performances, whereas in the direct program any slip passes directly to the audience and cannot be recalled.

FLINT IMPLEMENTS
Great and Small

By J. REID MOIR

As we all know, certain kinds of reptiles of the remote geologic past started their careers when they were of very small size and finished their earthly course when they had developed to gigantic and preposterous dimensions. In fact, so unwieldly and immense did some of them become that it has been supposed their disappearance was due to their great increase in size which made it impossible for them to adapt themselves to their environment. Whether, however, this theory is correct or otherwise, it is of considerable interest and, strange to say, has some kind of bearing upon certain problems which students of early man find themselves called upon to solve.



Drawings by the author

Figure 1: **A is a massive rostro-carinate from beneath the very ancient Red Crag of Suffolk. B is a diminutive rostro-carinate from the much later, second interglacial age in Suffolk**

THANKS to the researches which in recent years have been carried out in deposits containing the earliest flint implements, it is possible, and of much importance, to trace what may perhaps be termed the career of any particular type of artifact from its first appearance until it passed out of use. When this is done it is realized that in most cases flint implements, unlike ancient reptiles, first appear of a very large size, and dwindle finally to minute, and as it would seem, to almost useless proportions. It must of course be clearly understood that the earliest examples of any particular type of flint implement are not all of great size. But although this is the case, it remains true that the majority of these examples are of massive porportions.

The reasons for this largeness are by no means easy of explanation. It is probable that the size of the raw material played an important part in the dimensions of the resulting implements, but this reason must not be over-stressed. For, although it would not be possible to make large implements from small nodules of flint, it would be quite easy to manufacture small artifacts from masses of flint, however big. Again it may be imagined that the earliest men were of great muscular strength, possessing hands much larger than those of their descendants, and this may be regarded as a probable explanation of our problem, as certain very ancient flint implements which have been found are provided with what appear to be carefully prepared hand grips which were evidently not meant for hands of the span of those of today.

Whatever may have been the cause, a survey of the flint implements made by prehistoric man will show that, generally speaking, the more ancient these specimens are, the bigger will be their size. There is a difference of the same order to be observed in the flaking as, in the older implements, the flake-scars are large and caused evidently by powerful blows, and this peculiarity becomes progressively less marked as the specimens of later cultures are examined. It must not, however, be imagined that the fact of an implement being coarsely flaked points to a lack of knowledge of flint flaking on the part of its maker. In fact, in my experiments I have actually found it more difficult to produce say, a hand axe, solely by the removal of large flakes than by the detachment of smaller ones. It is, of course, true that the later implements exhibit a more delicate outline, or form, than the earlier, but this does not in every case mean that the former are more skilfully made than the latter. For instance, it would not be correct to claim that a Mousterian *racloir* exhibits more skill in flint flaking than does an early Chellean hand axe, and of the two types I would regard the Mousterian specimen as being much more easily produced.

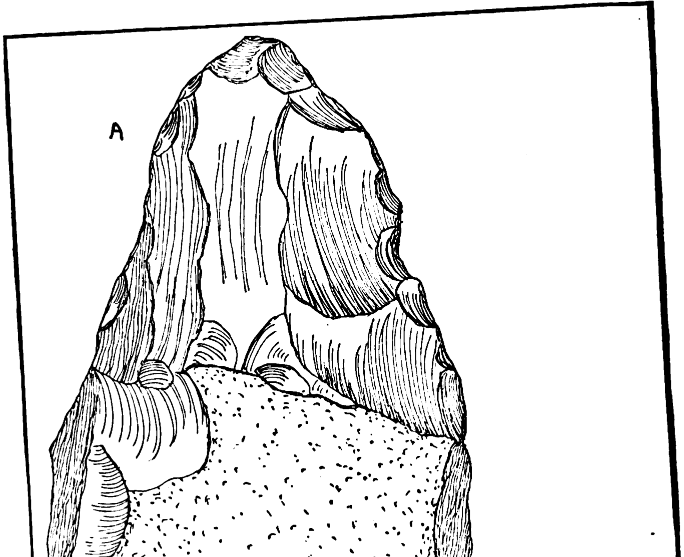


Figure 2: **Another contrast. A is a huge seven-pound hand axe and B is a diminutive hand axe**

ALTHOUGH up to a point it is legitimate to compare the invention, age, long use, and gradual discarding of any particular type of flint implement with the appearance, existence, and final disappearance of some form of life, yet I know of no particular form of artifact which, like certain animals, became actually extinct, and left no descendants. Even in Neolithic times the most primordial types of implements, the eoliths and rostro-carinates, appear occasionally; and other forms, clearly related to earlier artifacts, occur at that epoch. Neither is it possible to hold that such and such an implement appears first at a certain period and, as it were, to claim a "special creation" for it at that time; for a careful collecting and examination of the flaked flints of earlier epochs, will usually reveal forms clearly ancestral to that under discussion. As an example of this, mention may be made of the *tranchet* axe found particularly in the shell mounds of Denmark which are of early Neolithic Age. It is not long since this type of implement was regarded as making its first appearance at this epoch but recent researches have shown it to occur in the lower Paleolithic cultures of South Africa, at the lower level at Le Moustier in France, while I have found an example in a "floor" of early Mousterian Age in Suffolk.

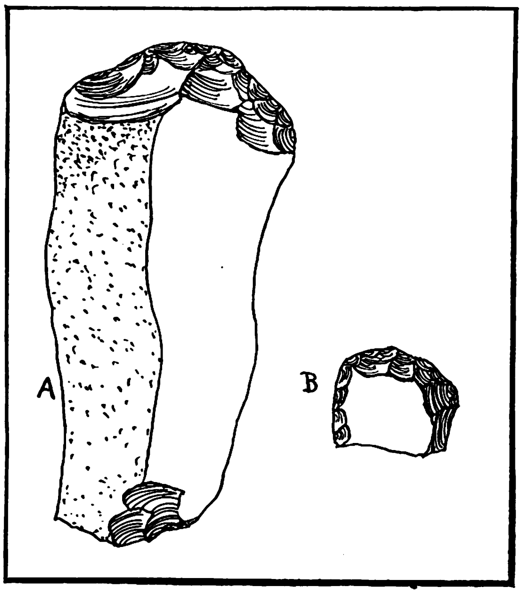

Figure 3: **Contrast *A*, a seven-inch Mousterian (Neandertal) scraper, with *B* of Bronze Age from burial in Suffolk**

It becomes clear, therefore, that modern work in archeology is demonstrating that no prehistoric culture can be regarded as in a "water-tight" compartment, but each is indissolubly related to that which goes before and to that which comes after. But at certain epochs particular types of implements made occasionally in earlier times, suddenly, for some unknown reason, sprang into favor and these types became the dominating artifacts of those epochs.

THE problem of the implement of minute size is by no means easily solved. In Figure 1 are shown two rostro-carinate specimens, the larger found beneath the very ancient Red Crag of Suffolk, and of several pounds in weight, while the smaller, found in beds of second inter-glacial age near Ipswich, is a true rostro-carinate but of very small size. There is no difficulty in realizing the uses, such as chopping and picking, to which the larger of these two specimens could be put, but to what useful purpose can the smaller be referred? Again, in Figure 2, a huge hand-axe from the Cromer Forest Bed of Norfolk is illustrated beside a very small example of the same type of implement found in a floor of Upper Paleolithic age at Ipswich, Suffolk. Here the same difficulty of assigning a use for the smaller artifact arises, as it does also in the case of the scrapers (Figure 3) and *tranchet* axes (Figure 4).

I have sometimes wondered whether these very small implements of certain types were ever made for any utilitarian purpose but represent, rather, "models" of artifacts, the forms of which had been handed down by tradition. We know that in the Bronze Age flint scrapers, for example, were occasionally scattered over the burial sites of that period, thus showing that these specimens had acquired some magical value. It seems possible, therefore, that in the Stone Age some ancient types of implements were made also for the same occult reason and this may explain the minute artifacts to which attention is drawn in this article.

But while this may be the case, such an explanation can not apply to the widespread "pigmy" culture which marks the closing phases of the Stone Age. At this epoch, from the Vindhya Hills in India right across to western Europe and Britain, a remarkable flint industry is found in which many of the implements are literally of microscopic size. Some of them are as small as a grain of rice and exhibit edge flaking which is so minute that a strong lens has to be used in order to see it satisfactorily.

THERE is, of course, no doubt that these specimens are the work of man but it is also evident that their makers must have been possessed of eyesight much keener than the average person of today, who, with unaided vision could not flake flints in such a manner. Some of the specimens assume geometrical forms and are believed to have been inserted in pieces of wood as harpoon barbs. But this explanation does not cover all the types of pigmy flints, and the uses to which many of them were put remain obscure.

Associated with these very small artifacts and obviously of the same age are numerous implements of much larger size, thus showing that the smaller were made for some specific purpose. The notion was at one time put forward that these microscopic implements were made by a race of very small people, of about three feet in height. But this view was soon demolished by some one who pointed out that if a flaked flint one eighth of an inch in length pointed to its maker standing only three feet, then by the same reasoning a specimen 10 inches long must have been produced by a super giant. When, as in very ancient specimens, definite hand grips are found to have been produced upon implements, it is possible to come to a conclusion as to the size of the hands of those days, but to judge of the height of past races of mankind by the length of the implements they made is patently absurd, for this would connote the previous existence of numerous races of true story-book giants, and we are sure there were none.

The fact of the matter is that our knowledge of the uses to which many stone implements were put is almost negligible. We have at present reached the stage when it is possible to claim on scientific grounds that certain examples exhibiting flaking have been shaped by man. Further, we can with equal certitude state that these specimens were weapons, implements of one kind or another.

BUT it is not possible for us, and it may never be, to assert that these artifacts were put to this or that particular use. It is clear, however, that the great majority of the humanly-flaked flints which are discovered are merely tools with which other things of wood, ivory, and bone were made. But, except in a very few cases where conditions have been favorable to the preservation of such specimens, they have failed to survive the vicissitudes of the past. This fact should always be kept in mind when attempting to reach a conclusion as to the state of culture existing among any prehistoric people, as the flint implements they made are only the indestructible residue of their industry, and to judge of their condition of advancement merely by taking into account this residue, must clearly be entirely misleading.

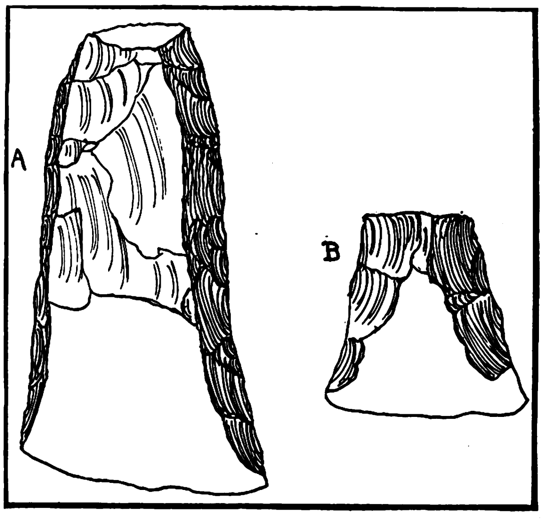

Figure 4: ***Tranchet* axes great and small. *A* is from Paleolithic deposits in South Africa and *B* is from much more recent beds near Ipswich, Suffolk**

Index Globe for Study of Geography

THE self-pronouncing dictionary now has a rival in geography in the form of a unique globe which was shown at the American Library Association conference in Los Angeles recently. The globe was invented by Charles M. Williams, a resident of Los Angeles for 40 years.

By means of paper rolls inside the globe, the location of more than 43,000 towns, mountains, rivers, and bays is indicated automatically through a small window when a handle at the bottom of the globe is turned. When the location is noted from the inner index, the globe may be turned, and the place found immediately by means of a special finder scale. If the globe is turned farther, a description of the country, a list of its products, its climate, and photographs of scenes in the country may be seen through a second small window on the side opposite the first. This globe also shows the point in the world where any constellation of stars will be visible at a specific time, and the point on the earth where, on any particular date, the sun will be directly overhead.

As the handle is turned, the index gives the information desired

Hudson River Bridge Cables Completed

THE spinning of the last wire for the last cable of the Hudson River Bridge at New York, took place shortly before noon on August 7, thus marking the completion of a major and probably the most spectacular phase of the building of the structure. The occasion was informally observed at the Jersey end of the span. Commissioners of the Port of New York Authority, which is constructing the bridge, and a number of other interested persons assembled on the Palisades as the last wire, to which was attached a small American flag, came across the river from the Manhattan side.

The spinning of the four enormous cables was completed in less than 10 months, the first permanent cable wire having been strung on Friday, October 18, 1929. The number of men engaged in the spinning operation was approximately 400. One man was killed at the New York anchorage while setting up spinning equipment, but none was seriously injured or killed during the spinning operation. Only about 27 days were lost due to inclement weather conditions.

Complete details of the cables and the methods of spinning were given in an article in the January, 1930, issue of SCIENTIFIC AMERICAN.

Illegal Guns Slaughter Waterfowl

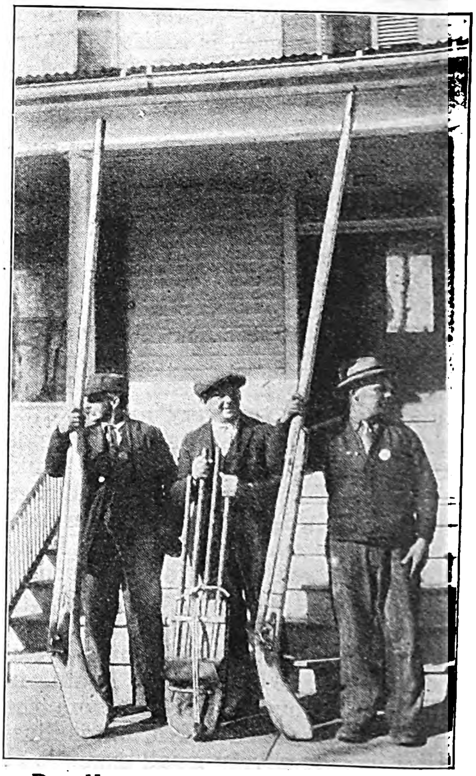
DESPITE the fact that both federal and state laws prohibit the use of guns larger than 10-gage in taking waterfowl, game wardens from time to time discover elaborately built "artillery" used for this purpose. Every person, whether he be a sportsman or not, should assist the authorities in wiping out this illegal method of hunting and use every effort to assist in securing conviction of the violators.

In the accompanying photograph are shown three illegal guns captured by game wardens in Maryland. The one in the center was captured last January by Aleck Tyler on Fox Island, which lies along the Maryland-Virginia boundary line. It consists of four barrels, each of a different length and having muzzles one inch in diameter, all bound to a large oak block by means of an iron band. The total weight is 125 pounds. Carved in the wood at the base of the barrels is a groove for powder which is ignited by means of a percussion cap fired by a hammer on the right hand barrel. This arrangement causes firing of the four barrels in rapid succession.

The two long guns, one eight feet and one nine feet long, and weighing 90 and 100 pounds respectively, were confiscated by Warden Tyler, together with two Deputy Wardens and Orin D. Steele, United States Deputy Game Protector. These guns are made of two-inch galvanized piping with one end brazed to form a chamber, mounted on home-made stocks. The charge for one of these guns consists of about one fourth of a pound of powder and one pound of shot.

Such guns are used by violators of wild fowl laws for hunting wild fowl at night. The large single barrel guns are usually locked to a skiff, the barrel projecting over the bow and the breech supported by some object at the butt and fastened in such a manner as to take up the recoil. The battery type is usually mounted on a swivel. These guns are very destructive and will kill at one firing from 100 to 150 birds and cripple many more.

The hunter who follows this method of



Deadly guns for slaughtering waterfowl, confiscated in Maryland

shooting wild fowl is very hard to apprehend since he uses a small skiff with a short paddle, sneaking at night into large rafts of waterfowl on their feeding grounds. Since the water is shoal on these grounds, it is very easy for the pot-hunter to get within range of the birds before they become suspicious.

Entoptical Effects—Can You See Them?

MR. L. F. CULVER of Gautier, Mississippi, one of our readers, sends us the following note concerning a peculiar effect in the realm of physiological optics. He describes phenomena which other readers may be able to duplicate.

"Many times," Mr. Culver writes, "while lying on the ground with a straw hat over my face I noted that for each tiny opening through which light came I saw a round light spot about one fourth inch in diameter and with a dark center. At length I saw that these light spots were all of the same size, and I also observed that the dark centers were of irregular form, but all exactly alike in detail, except that the spot seen by one eye was totally different in form and detail from that seen by the other eye.

"Then I noticed on successive days that these dark spots always looked exactly as at first. As their form was not at all dependent on the form of the openings in the hat through which the light came, I concluded that what I was seeing was within the eye itself and must be the blind spots on the retina, that I had learned of in my school days.

"I tried other ways of seeing them and discovered much that was unexpected and very interesting and beautiful. This, I found, required considerable patience and perseverance, but the reward was ample. I think it best, however, first to try the method described above.

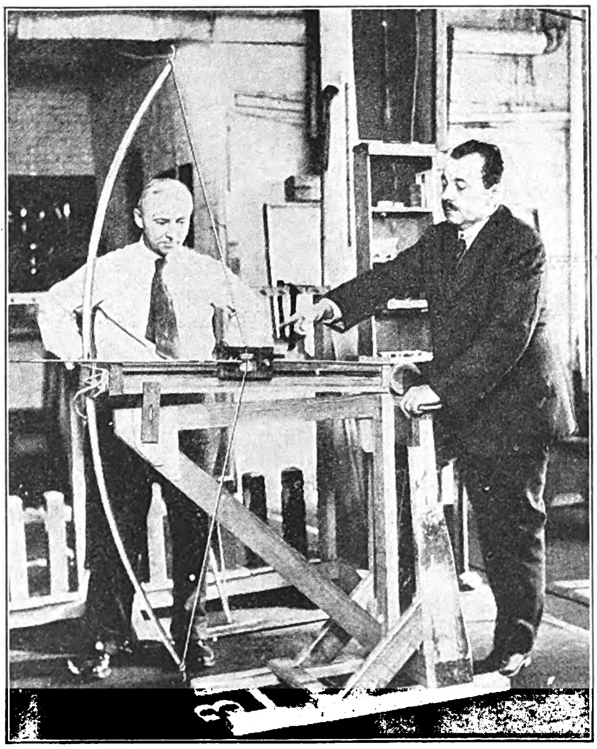
"At night sit with the side of the head toward the source of light and facing a darkened part of the room or a door opening into a dark room. Hold about one inch from the eye farthest from the light some small, polished, spherical surface of one-eighth inch or less in diameter to reflect the light into the eye. This illuminates a part of the retina. Near the center of the illuminated part will be seen the blind spot. The dark nucleus of the spot evidently is bordered by a row of highly sensitive nerve filaments which appear like a row of brilliant bright dots close together. In my left eye there are three small blind spots outside of the main spot. The borders of these also are studded with bright points. The group reminds one of a group of sun spots seen through a telescope. Under stronger illumination, as with direct sunlight, bright points appear, sparsely scattered over the entire blind area, and much new detail is seen. Whatever the reflecting surface used, these spots change their form. The amount of detail seen varies greatly with the degree of illumination."

These phenomena are known as "entoptical" effects and are described in works on physiological optics, most comprehensive of which is the famous "Treatise on Physiological Optics" by the great German authority Helmholtz. This three-volume work of 1700 pages is an old standby to all physicists and opticians. Recently it has been translated, and thus made easily available to English speaking readers, by Professor James P. C. Southall of the Department of Physics at Columbia University, author of "Mirrors, Prisms and Lenses," himself an authority on optics.

"Under suitable conditions," says Helmholtz, "light falling on the eye may render visible certain objects within the eye itself. These perceptions are called entoptical. . . . There are some objects in the eye, particularly the blood vessels of the retina, which fulfill the latter condition by being very close to the sensitive membrane and therefore in position to cast shadows on the retina." Fully to describe these and a wider variety of entoptical effects would, however, demand as much space as is devoted to them in Helmholtz' treatise.

While Mr. Culver's discovery is not new to science, he made it independently. When his note, as reproduced above, was submitted to Professor Southall for opinion, the latter commented, "I think Mr. Culver deserves much credit for having made these experiments for himself."

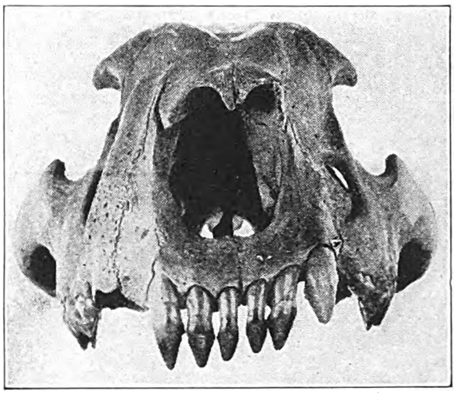
Perhaps others of our readers can duplicate these effects.



As the age-old sport of archery takes a new hold on the interest of thousands, problems of constructing bows and arrows have had to be solved anew. Much success has attended the efforts of the manufacturers, but there is still much to learn. The illustration shows a new machine displayed some time ago by the archery club of Seattle, Washington, for testing the accuracy of arrows. With this home-made contraption, arrows can be tested so that their feathers may be trimmed, thus making possible the shooting of an entire quiver of arrows under any given set of conditions

When the Tiger Lost a Saber

IT is said that Mrs. Paleolith would quiet her young Paleoliths by saying she would call Old Saber-Tooth; and these giant long-toothed cats were indeed fearful-looking creatures. Once in a while saber-tooth skulls from which a saber 10 inches long had been lost, are seen, but the animal had survived the loss bravely. It is thought that these toothed cats used the long sabers for stabbing the prey in order to drink the blood, but it was possible, when a saber was lost, to survive by eating flesh. This particular tiger lost the saber when young, the saber-tooth being broken off far up in the socket. Its loss produced a curious asymmetry due to the necessity of filling in the large socket. In loosing a saber the great cat had had its face lifted. The front teeth in the tiger's left jaw are elevated and the bones reduced.



When this tiger lost one of its saber teeth at an early age, its jaw grew asymmetrical, one-sided

Chemistry and the Old Rag Man

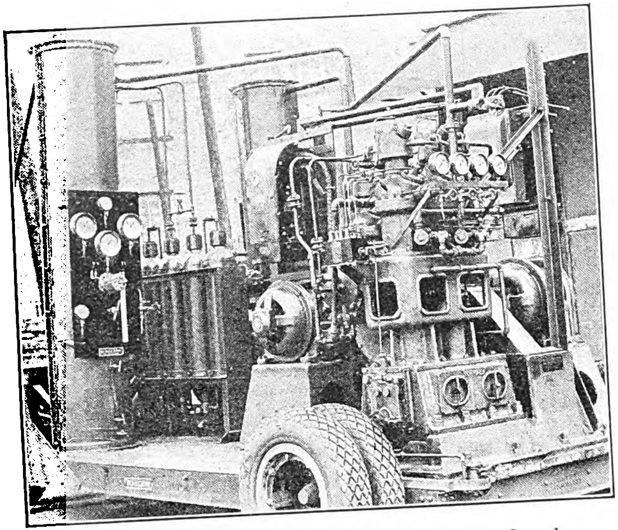
RAYON has given us wonderful and beautiful varieties of cloth but, when the glossy fabric has served its purpose and found its way into the rag bag, it is not popular with the rag man. Before the advent of rayon, "old rags" were the raw material for the finest grades of writing paper. Recent tests by the United States Bureau of Standards disclose the fact that rayon rags are valueless for this purpose, and may actually be detrimental. Laboratory tests were conducted at the bureau to determine the paper-making quality of rayon when subjected to the same treatment as rags in the production of fine papers.

Cotton and linen fibers are commonly used for papers, such as bonds and ledgers, on account of their strength and durability. In addition to their value in these respects they are used in the manufacture of papeteries and other fine writing papers, as well as to impart softness and other desirable characteristics of surface and finish. The presence in rag stock of any fiber which would affect these qualities of paper is undesirable.

Samples representative of the four general processes of rayon manufacture—viscose, nitrocellulose, cuprammonium, and cellulose acetate—were included in the tests. The equipment employed in the preparation of the pulp and its subsequent conversion into paper was on a laboratory scale and is that used at the bureau for the preliminary tests of all paper-making materials under investigation. The caustic soda and lime processes were used in the cooking operation. Paper-making stock was prepared from the pulp, alone and in admixture with sulfite pulp, and converted into paper on a sheet mold.

Owing to loss of strength when wetted, the rayon filaments tended to break into short lengths during the preparation of the paper-making stock without the fibrillation and fraying necessary for good felting properties. As a consequence, the all-rayon sheets lacked the strength to withstand the handling necessary in the pressing and drying operations, and the pliability characteristic of rag papers. Likewise, sheets made of rayon in admixture with sulfite pulp were considerably weaker than those made from sulfite alone.

Since increasing amounts of rayon are being found in the rags and textile waste used in rag-paper manufacture the test data are believed to be of value to that industry.



When helium becomes diffused with ordinary air—a condition that might take place in a dirigible due to leakage of the gas envelope—its "lift" is decreased in proportion to the adulteration. Because of this fact, the mobile helium re-purifier shown here was built for the Goodyear-Zeppelin Corporation. It removes air and any other diffused gas from helium by the process of freezing out, as explained in the text

A Chemical Service Station for Dirigibles

In a few years, when air travel is as commonplace as railroad travel today, machines like that pictured here may become as familiar to travelers as the workman who taps the axles while the train is standing in the station. This trailer full of motors and compressors will draw up alongside your dirigible and will start to work, drawing the helium gas out of the balloonet, removing the air that has mixed with it, and returning it to the ship with its full lifting power restored.

The mobile helium re-purification plant was built for the Goodyear-Zeppelin Corporation, of Akron, Ohio, by the Helium Company of Louisville, Kentucky. The entire plant, with a capacity of 1500 cubic feet of gas per hour, is mounted on a pneumatic-tired trailer body and can traverse any terrain which a truck can negotiate.

The mobile plant consists essentially of two compressors, one handling air, the other helium. The air compressor supplies air at high pressure to an expansion column, which serves to liquefy a portion of the air, forming a cooling bath at a temperature of —170 degrees, Centigrade. The second compressor forces helium at 2000 pounds pressure through copper coils immersed in this liquid air, with consequent removal of impurities by liquefaction. The helium passes through nearly a half-mile of copper tubing, and is finally discharged at a purity of 98 to 99 percent to any desired point and at any pressure up to 2000 pounds per square inch. The loss in repurification is approximately 1 percent.

The mobile helium repurification plant was designed by R. R. Bottoms, director of research, and E. G. Luening, executive vice-president of the Girdler Corporation, which operates the Helium Company. These men were also responsible for the development of the special fuel gas used by the Graf Zeppelin on its first return trip to Friedrichshafen from the United States. *—A. E. B.*

"Jake" Paralysis

During the past few months thousands of cases of paralysis from drinking bootleg Jamaica ginger have occurred, principally in the southwestern portion of the United States. Studies made by chemists indicate that the poisonous substance is a derivative of coal tar or phenol. Few of the patients have died, but practically all of them have developed forms of paralysis which seem to be fairly permanent. The nerves affected include those of both the arms and legs. The nerves conveying sense of pain, touch, and heat have not usually been disturbed, but in some cases the patients seems to lack also these sensations. In one instance in Oklahoma City a traveling man 66 years of age died following paralysis from drinking Jamaica ginger. Postmortem examination indicated that in some manner the poison had selected the nerve of motion in the arms and legs. The tissues of the brain were not apparently greatly influenced by the poison. Post mortem examination also revealed that death was apparently due to a previous kidney disease, complicated by his secondary illness, rather than to the Jamaica ginger.*—M. F.*

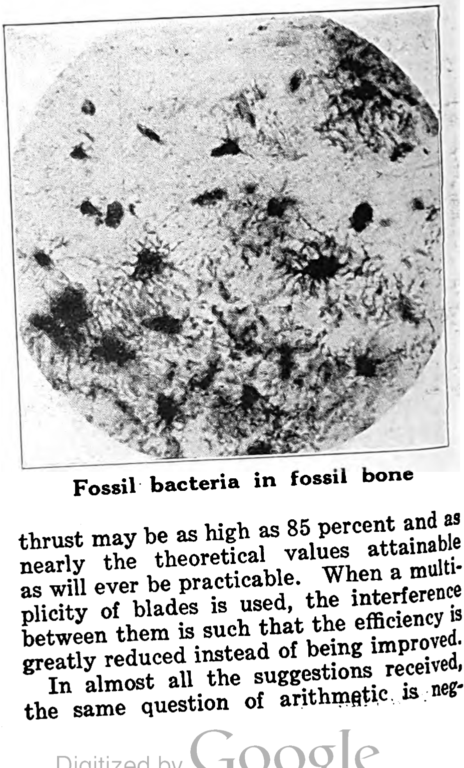
Ancient Bacteria Preserved in Fossil Bone

It has been a matter of surprise that such minute, delicate bits of protoplasm as bacteria should be found in thin sections of bone many thousands of years old. Yet in the bone of an ancient tiger, under the microscope, are found undoubted germs resembling some of the bacteria of today. The picture shows, at a magnification of 400 diameters, colonies of bacteria in the minute, thread-like canals leading out from the bone cells which appear in the picture as dark diamond-shaped bodies. It is not known whether or not these ancient germs brought on disease but it seems likely that they were the germs of decay.

Peculiar Aviation Inventions

We are constantly receiving suggestions for peculiar types of aircraft and aviation accessories, some provocative of thought, some merely of amusement. The inventors, however, are in dead earnest, and full of the desire to advance aviation. Here are extracts from an anonymous letter, with the envelope bearing a Canadian postmark. "Dear Sir. I am quite unknown to you and you are to me. However I do not hesitate to address you this letter; for if the idea that it contains is good it matters little to know whence it comes but it matters only to use it. So I desire to remain unknown but I desire also an experiment to be done, that, in my opinion will give the best results . . . The motor of the plane works in the air by means of the propeller. But the propeller with two blades is an instrument with which the motor can work but little in the air in one turn . . . . however let us consider that to the two blades of the propeller, one can add 16 other blades on the same circumference. That makes a propeller with 18 blades; it is the American Wheel. . . . To be used for speed it is necessary for a motor to make much work during a turn."

The suggestion is a typical one. Such inventions always come down to a question of arithmetic. It seems at first sight plausible that with only two propeller blades on a shaft, the intervening air is not worked upon properly. But when the suggestion is examined technically, it is found that two propeller blades already take up the entire power of the engine, and that the efficiency of the two-bladed propeller in producing thrust may be as high as 85 percent and as nearly the theoretical values attainable as will ever be practicable. When a multiplicity of blades is used, the interference between them is such that the efficiency is greatly reduced instead of being improved.



Fossil bacteria in fossil bone

In almost all the suggestions received, the same question of arithmetic is neglected. Dozens of plausible helicopters are suggested, with some screws for lifting, some for propulsion, and so on. There is nothing theoretically wrong in such helicopters, but when the invention is examined it is found that the inefficiency of the various elements, the complication of the mechanism, and failure to consider certain factors of stability and control make the idea quite impracticable. There appears to be in the United States an inexhaustible fund of inventiveness and courage. The prime necessity is to add to mechanical instinct at least a modicum of analysis with reference to air forces and efficiency. At the same time, one dare not predict that some instinctive mechanic will not yet contribute to our knowledge without such basic analysis!—*A. K.*

A Chemical Paradox

NOTABLE among the triumphs of industrial chemistry during the past decade has been the development of commercial processes for the synthetic manufacture of ammonia and nitric acid. Because of the efficiency of these new methods, ammonia is being sold at prices which make it attractive in many new industrial roles, some of which were described in an outstanding paper presented by Jasper E. Crane, of the duPont company, at a recent meeting of the Manufacturing Chemists' Association.

Among the most attractive of the newer uses for ammonia is its application as a source of hydrogen, particularly for welding. It seems, offhand, to be paradoxical to state that it is economical to combine hydrogen with nitrogen to form ammonia, then to separate the two gases again in order to obtain the hydrogen. The answer to the paradox lies in the fact that one cylinder of ammonia, when "cracked" is equivalent to about 17 cylinders of hydrogen. As the principal part of the cost to the user of hydrogen is the cost of the cylinder, he finds that he saves about one-half by buying 17 times the volume of hydrogen in a single cylinder. Simple, inexpensive apparatus has been developed for cracking the gas by use of an electrically heated catalyst.

An even more striking reduction in cost is that of nitrogen made by the cracking process. The cracked gases are burned in air, producing water and nitrogen. One cylinder of ammonia, in this case, is equivalent to about 36 cylinders of nitrogen at one ninth the cost.

Other better-known uses, of course, are much more important as tonnage markets for ammonia. These include the production of synthetic organic chemicals in great variety; nitric acid and synthetic sodium nitrate; fertilizers; nitrided metal products; and its uses as a cheap alkali.—*A. E. B.*

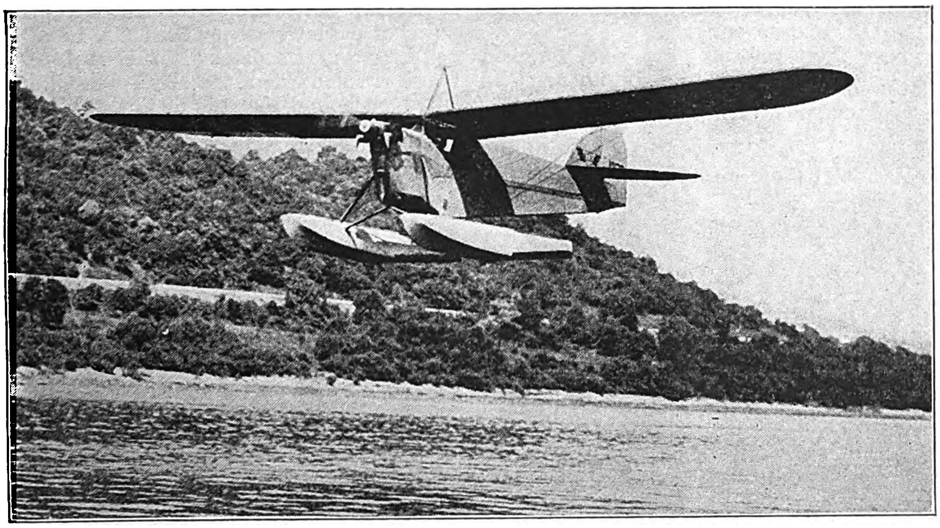
An Interesting Light Plane

THE popular interest in gliders has been followed by enthusiasm for the light plane. One of the most successful of these small planes, with success measured not only by flying ability, but by large sales also, is the *Aeronca* built by the Aeronautical Corporation of America. This plane is equipped with a relatively small engine of the two-cylinder opposed type, 4 1/8-inch bore and 4-inch stroke, rated at 30 horsepower at 2500 revolutions per minute. The weight empty is 385 pounds, the disposable load (with one occupant) 315 pounds; thus the total or gross weight is only 700 pounds. The span is 36 feet and the wing area 144 square feet. The top speed is given as 85 miles per hour, the landing speed as 31 miles per hour, and the initial climb as 550 feet per minute. Such performance is quite adequate for private flying, except for cross-country work under adverse wind conditions.

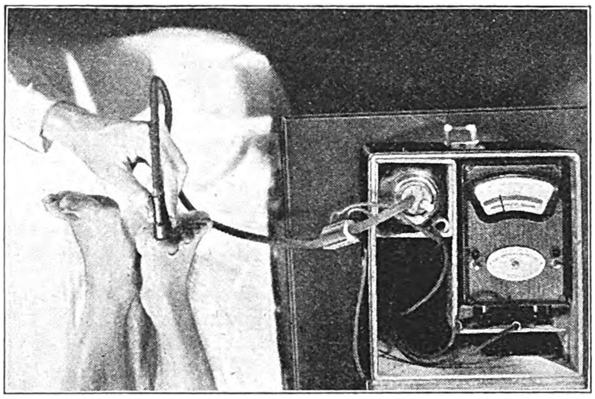
The main interest of the *Aeronca* from a flying point of view is in the low wing loading, the use of relatively large control surfaces, and of large dihedral and vertical fin areas.

The low wing loading, 4.8 pounds per square foot of wing area, means low landing speed, quick getaway, and short pull up. This makes for safety and for the possibility of using small fields.

The large dihedral (raising of the wing tips relative to the center) makes for stability in a side slip. The large vertical tail surfaces give weather-cock stability, the plane swinging into a side wind instead of swinging dangerously away from it. The large control surfaces, on the other hand, make for ease of control in spite of the inherent stability. The aerodynamic conception, although not exactly novel, makes for ease in flying. Machines of equal stability and the reasons for such stability have been known since 1910 or thereabouts. But it is gratifying to see designers take perfect stability as their objective again. If there is to be private flying, machines must nearly fly themselves. There is but one serious disadvantage to such a lightly loaded plane: gusty weather is apt to result in difficulties near the ground and considerable bumpiness aloft.—*A. K.*



Quite adequate for private flying, this plane, empty, weighs 385 pounds



Most of us are familiar with the clinical thermometer but few, among laymen, realize the necessity for taking temperatures on the surface of the body. The illustration shows an improved electro-thermal instrument for measuring body surface temperature and the text herewith explains the need for it

Body Temperature Measurement

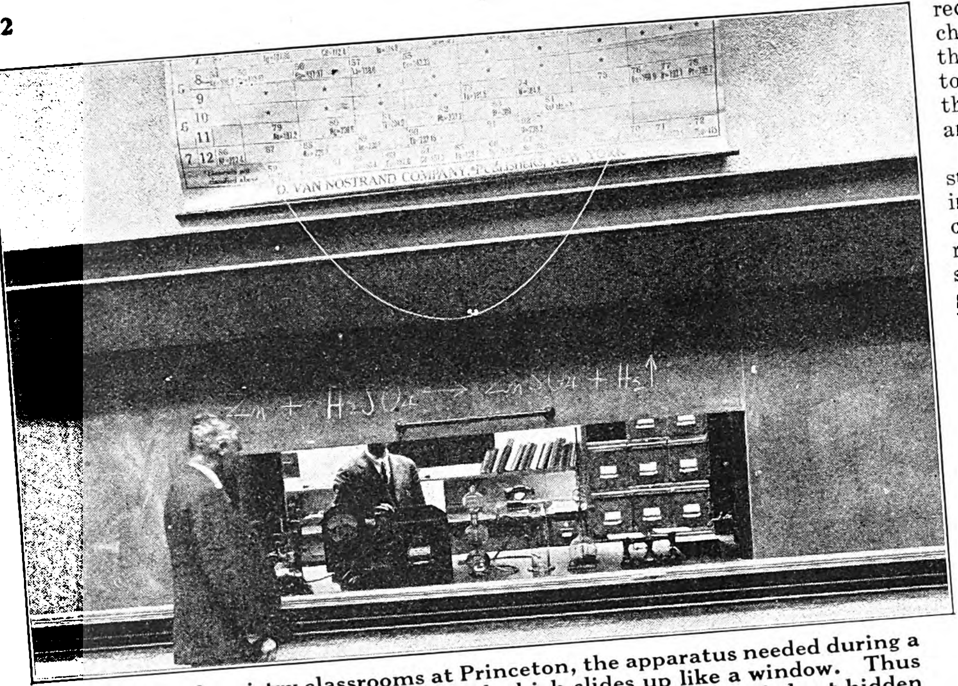
THE measurement of the temperature of the human body on the surface and at various points represents one of the most important observations made by the physician in the diagnosis of disease. It has been recognized for years that infection produces congestion and fever. There is increased flow of blood to the part involved which is responsible for the changes that occur.

Investigators in the Mayo Clinic have recently developed an electrothermal instrument for measuring surface temperature and also for measuring temperatures of various organs at any given time. In case the temperature of an organ or of the spinal fluid or of the brain is to be determined, a needle is introduced and by means of the thermocouple method the temperature at the point of the needle can be ascertained. The sensitivity of the electrothermal junctions is increased by putting four couples in series; the galvanometer is calibrated in degrees Centigrade. Thus it is possible to measure the temperature at any point in the body in 10 seconds, absolutely accurately, and within a fraction of a degree.—*M. F.*

Lightning and the Airplane

WALTER E. BURTON, writing in *Aviation*, describes some interesting experiments now being conducted by the Ohio Insulator Company on the effects of lightning on the airplane.

In a thunderstorm, lightning is more feared, but wind is much more dangerous.



D. VAN NOSTRAND COMPANY, PUBLISHERS, NEW YORK
Zn + H2SO4 → ZnSO4 + H2↑

In the new chemistry classrooms at Princeton, the apparatus needed during a lecture is kept behind this blackboard which slides up like a window. Thus while the professor lectures, attention-distracting equipment is kept hidden from the students although it is set up ready for instant use when needed

Nevertheless the effects and dangers of lightning are well worth investigating.

The lightning laboratory of the Ohio Insulating Company is unique. With new equipment being installed, the laboratory will be capable of producing a spark at more than 3,000,000 volts pressure, nearly 30 feet long. In an open-air laboratory three transformers, the largest ever built, are used to produce the huge spark. The units are arranged in steps on a special porcelain tile base; the highest stands 50 feet above the ground. A number of oscillators are available to produce a continuous spark discharge. A camera with a shutter operating at 1/50th of a second is used for photographic studies of the flash.

At one end of the open air laboratory, a system of poles, guys, and insulators will allow the suspension of airplanes as large as a Ford tri-motor for experimental purposes. Because wind may blow discharges to one side, the airplane is in a field which is sheltered by groves of trees. So far experiments have been made only on airplane models. Later a full-size plane will be suspended with every part complete, the gasoline tanks full, and the engine running. It is not yet certain, however, whether the experiments with gas aboard and engine running will be possible without undue danger.

One problem has already been solved: a plane can be struck, can deflect a lightning discharge and become part of its path as it travels from cloud to cloud, or from cloud to ground. Among the many other problems to be investigated systematically are:

If a plane is struck, what is the probable effect on pilot and passengers?

If a lightning discharge takes place near a plane without actually striking it, will the pilot receive so large a shock as to lose control temporarily?

How vulnerable is the ignition system?

Do the exhaust gases, because of their ionizing effects, create a path for, and attract the lightning?

What is the fire hazard for tanks, fabric covering, and so forth?

What happens when metal parts are not completely bonded? Will sudden currents of several hundred thousand amperes passing through imperfectly bonded joints fuse the metal parts instantaneously?

We shall await with great interest the results of the experiments.—A. K.

Germans Isolate Ethyl Radical

POLITICIANS have definite, though varying, ideas of what a "radical" is, but when the chemist refers to a "radical" he means something quite different. In chemical parlance, a radical is a certain definite combination of atoms which stick together persistently and act, chemically, as a single atom. Thus, the two elements sulfur and oxygen are prone to link together as the radical SO_4 and to retain the identity of their union in compounds such as sulfuric acid, (H_2SO_4), calcium sulfate, ($CaSO_4$), and so on.

Now these radicals have been assumed to exist for years, although no one has ever seen any SO_4—it doesn't exist alone. Neither had anyone ever seen the important radical C_2H_5 which is part of the molecule of ethyl alcohol, (C_2H_5OH), until recently. Now, however, two German chemists report that they have isolated the radical C_2H_5—an announcement which to a chemist is about as startling as saying that a soul has been separated from a man and put in a glass case for observation.

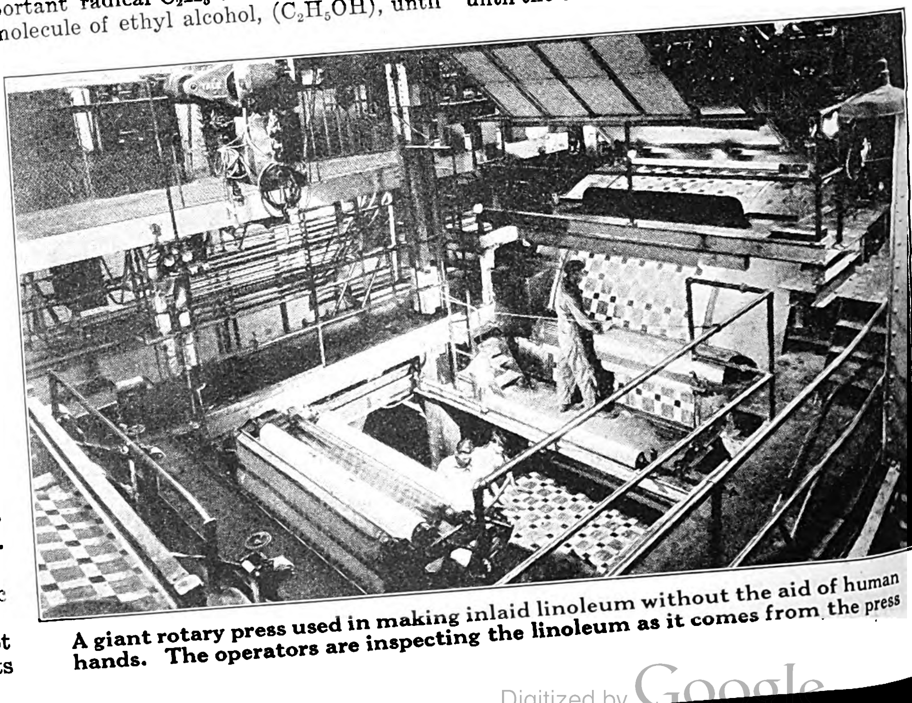
Professor Paneth and W. Lautsch have succeeded in producing the radical ethyl in a free form by the thermal decomposition of the vapors of lead tetraethyl in a current of hydrogen under diminished pressure. The ethyl radical is just as aggressive as the methyl recently isolated by Paneth and Hofeditz. Free ethyl converts such metals as lead, zinc, antimony, and cadmium into volatile compounds, which are clear as water at room temperature and 760 millimeters pressure. —*A. E. B.*

An Industry That Grew from a Paint-Pot

A PAINT pot, accidentally left uncovered, furnished the clue to several great industries that have grown up since Frederick Walton found his paint covered with the tough skin of dried oil. In his efforts to make something useful out of that film, Walton eventually laid the foundations for the linoleum business, for he discovered that the dried oil could be ground up, mixed with granulated cork, and made to adhere to a canvas or burlap foundation. The inventor died recently at the age of 94, having lived to see a giant industry arise from his early experiments.

Although modern linoleum is characterized by a beauty and durability undreamed of in the early days of its manufacture, the process of manufacture is fundamentally the same as described in Walton's original patents. Linseed oil, pressed from flaxseed, is boiled to the consistency of molasses so that it will oxidize or dry out quickly. This same boiling process is the beginning of patent leather manufacture and that brings us to the place where our chemist friend, Professor J. S. Long, of Lehigh University, comes into the story.

Several years ago, a certain manufacturer of patent leather asked Dr. Long to tell him why the patent leather surface of shoes cracked when the shoes were worn. Dr. Long found that the boiling of the linseed oil was done in an empirical manner, the operator simply continuing the cooking until the oil felt about the right consistency,



A giant rotary press used in making inlaid linoleum without the aid of human hands. The operators are inspecting the linoleum as it comes from the press

when rubbed between the fingers. The chemist, knowing the fallibility of human judgement, began to investigate the reason why linseed oil "thickens" on cooking. He soon confirmed his suspicion that the change was due to an increase in the molecular weight of the oil. From there it was easy to develop a simple method of determining the molecular weight of the oil as the "cook" progressed, and to stop at exactly the right point. Thus, perfect uniformity of product is obtained, and the patent leather manufacturer is no longer subject to the troubles that were his lot when he depended on the guess of his workmen. This piece of research work was the starting point for a series of investigations at Lehigh University that have almost as much significance for the users of linseed oil as Walton's curiosity about the film in the paint pot.

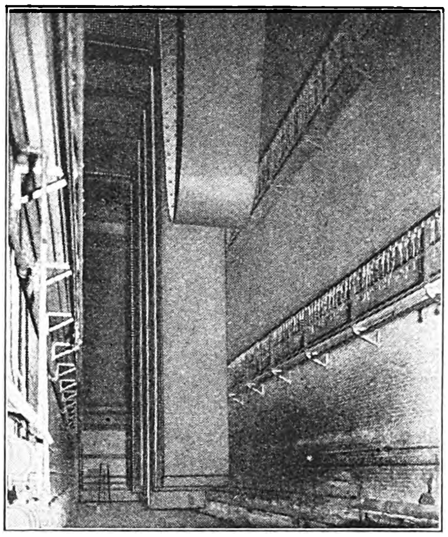
In the modern linoleum plant, the boiled linseed oil is run into a trough, from which it trickles down over sheets of scrim which hang from ceiling to floor of the oxidizing shed. The boiled oil oxidizes rapidly, forming the tough, elastic skin, which is ground up to a pulp and then mixed with rosin and other gums in large kettles. When the mixture cools, it is chopped up into convenient sized chunks and aged for several weeks before it is mixed with the finely ground cork. Color pigments are also added to the mix which is fed between huge steam heated rollers. The usual backing material is burlap. To obtain the many colorful designs which make printed linoleum such a popular floor covering, the plain material is run through massive printing presses, after which it is run into the "stoves" for drying and toughening. The more expensive grade, known as inlaid linoleum, is made by fitting vari-colored tiles of linoleum into a pleasing pattern, which is fused in position in hydraulic presses.—*A. E. B.*

"Sunshine" Lamps

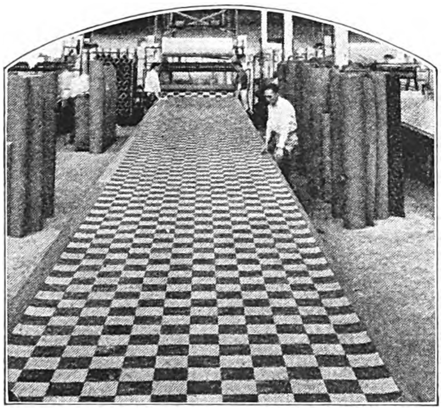
THE tremendous vogue of the use of lamps producing ultra-violet rays has caused considerable consternation among physicians who realize the limitation of these lamps for health and also the fact that there are all sorts of peculiar devices offered to the public, in many instances without any certainty that the device will actually produce good results or that it will provide the ultra-violet that the person wants. In order to bring some control into the field, the Council on Physical Therapy of the American Medical Association has issued a manifesto to manufacturers, defining the limitation of such apparatus and the claims with which it may be sold.

Because of the possible danger of lamps of high intensity, the Council has taken the stand that any "sunshine" lamp sold directly to the public should be so constructed that the radiant energy emitted shall not differ essentially from sunlight. In general, the Council believes that more conservative claims for the necessity of strong sunlight should be made by the manufacturers of lamps for home use, such statements being restricted to those which can be justified by conclusive scientific evidence. The Council is not convinced that human beings in good health require the great amount of ultra-violet energy which one is led to believe is the case from the advertising and descriptive matter pertaining to some of the so-called "sunlamps" sold to the public.

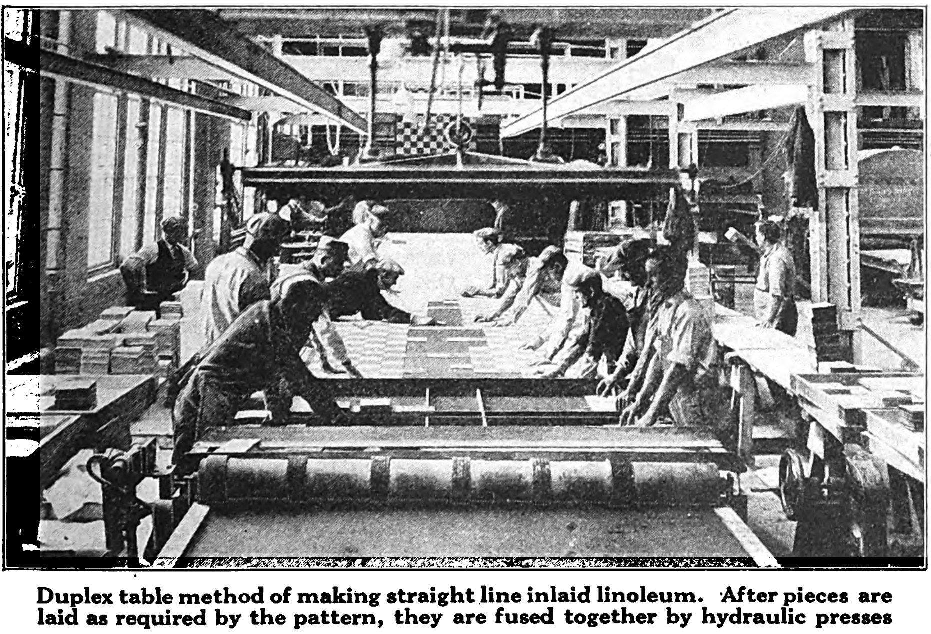
A number of the more responsible manufacturers have fully agreed with the opinion of the Council. The emission characteristics of their lamps are in essential agreement with the requirements established by the Council, and in their advertisements they carefully avoid making curative claims. Furthermore, in these advertisements attention is called to the advisability of consulting one's physician before exposing oneself to ultra-violet radiation.—*M. F.*



One of the "stoves" in which printed linoleum is "festooned" for final toughening and aging



Each roll of linoleum is inspected by experts but also is subjected to as many as 110 laboratory tests before it is ready for shipment



Duplex table method of making straight line inlaid linoleum. After pieces are laid as required by the pattern, they are fused together by hydraulic presses

Reforestation in 1929

REFORESTATION in the United States last year restored to tree growth a total of 111,175 acres, the Forest Service of the United States Department of Agriculture reports. This included the planting of 31,430 acres by 21 states and two territories, 5920 acres by municipalities, 25,088 acres by industrial organizations, 539 acres by schools and colleges, and 1516 acres by other organizations. Farmers planted 24,825 acres to wind-breaks and woodlots, and other individuals planted 3650 acres. The Forest Service planted 18,207 acres of land on national forests last year.

The First International Air Safety Congress

THE First International Congress for Safety in Aeronautics will be held in Paris during December, 1930. It is being organized by the *Comite Francais de Propagande Aeronautique*, under the presidency of the French Air Minister. Aircraft safety is not a matter of a single invention, but a question of improvement along innumerable lines. Nothing illustrates this fact as much as the program of the Congress, to which eminent authorities from every civilized country will be asked to contribute memoirs and investigations for consideration by the delegates.

The Congress is divided into seven groups and six sections. Group A will deal with safety organization in various countries and with the statistics of accidents. Group B will cover the general problems of air safety, under the following six sections: Safety of Materials; Aerodynamic Safety; Engine Reliability; Aids to Navigation; Meteorology and Aerology; Navigational Instruments and Radio Communications. Group C will consider the application of the best safety methods to all branches of commercial aviation. Group D is concerned with the physiology of the pilot and other questions of a medical aspect. Group E is concerned with the training of flying and ground personnel. Group F will take up methods of protection such as parachutes, means of preventing or extinguishing fire, et cetera. Group G will be devoted to lighter-than-air craft.

Valuable results may be expected from this well organized international gathering.

Explosion of Anesthetics

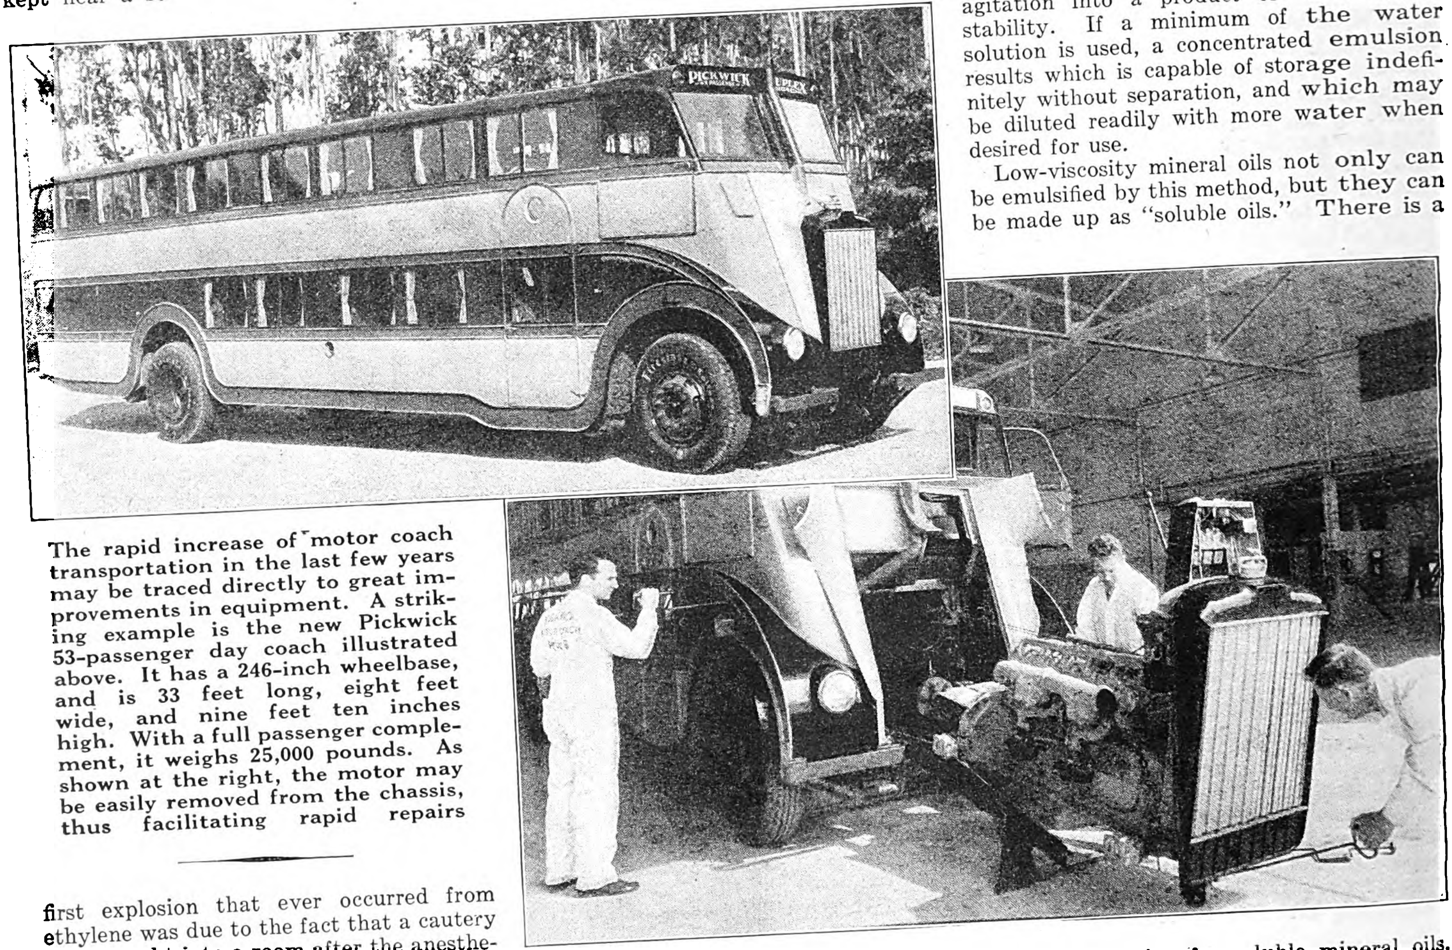
MIXTURES of air and ether, and of ethylene and air and of various other gases, occasionally explode. Obviously this constitutes a hazard in an operating room where a person is inhaling such a mixture of gases. It has long since been recognized that an open flame must not be kept near a source of ether vapor. The first explosion that ever occurred from ethylene was due to the fact that a cautery was brought into a room after the anesthesia apparatus had been removed but some of the gas was still in the atmosphere.

Recent studies indicate that electric sparks may be sufficient impulse to set off an explosion. The entire subject has been reviewed by Dr. H. B. Williams, who recommends the elimination of rubber from apparatus for giving anesthetics, making the equipment as far as possible conductive throughout. He also recommends metallic tubing and a general connection of the face piece to the tubing so that when removed from the face piece the upper part of the mask will remain in electrical connection with it. In this manner, the entire apparatus can be kept at a uniform electrical potential and no high voltage is likely to develop even if the apparatus is not grounded.

Among other precautions for preventing explosions are the following directions:

There should be provision for grounding the operating room personnel, to prevent sparks passing from their persons to the apparatus, which is more likely to occur in winter weather and in severe climates. If rubber soled shoes are worn, rivets of copper may be put through from inside to outside. Great care must be exercised in placing blankets removed from a warming closet on the patient. These, if very dry, may cause copious and intense sparks when unfolded or shaken. They might well be kept from becoming so dry. Blankets of wool may contain surprisingly large quantities of water without feeling damp; they may, in other words, be damp enough greatly to diminish the hazard of electric sparks without being in the condition popularly described as a "wet blanket."

Ethylene should under no circumstances be used in any operation in which an actual cautery or surgical diathermy apparatus is to be used, and ether should never be used in any throat operation in which a cautery or surgical diathermy or similar apparatus is required. Care should be taken, especially in very dry weather, not to comb or stroke the patient's hair until the ethylene has had time to become thoroughly dissipated. It would be well to wrap the hair in a linen binder during and immediately after the operation.—*M. F.*



The rapid increase of motor coach transportation in the last few years may be traced directly to great improvements in equipment. A striking example is the new Pickwick 53-passenger day coach illustrated above. It has a 246-inch wheelbase, and is 33 feet long, eight feet wide, and nine feet ten inches high. With a full passenger complement, it weighs 25,000 pounds. As shown at the right, the motor may be easily removed from the chassis, thus facilitating rapid repairs

"A Good Mixer" Welcomed in Industries

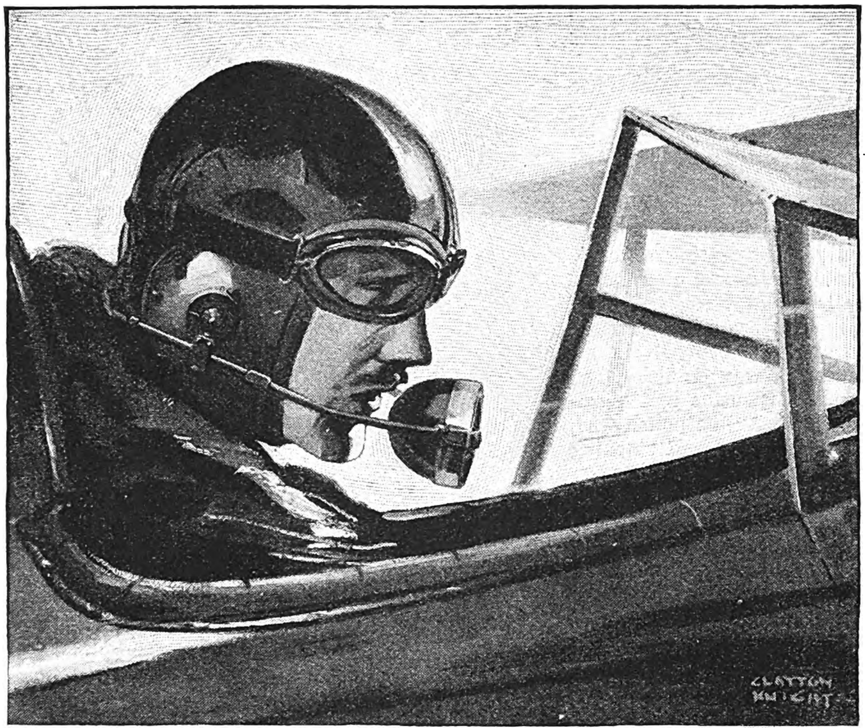
THE word "emulsion" always brings first to our mind a certain patent tonic which we were bribed and cajoled into taking before meals in the fast receding days of childhood. Emulsions, however, play a very important and ubiquitous part in a great many commercial products which are not related to medicine. The suspension and dispersion of fats, oils, and waxes in a liquid medium with which they are not naturally miscible is a basic step in the manufacture of a wide variety of useful substances. For this reason, the recent discovery that the compound, triethanolamine induces emulsification to an astonishing degree, is of prime importance.

Ordinarily, emulsification has been accomplished by slow mixing and vigorous stirring. In contrast, when an oil solution of a fatty acid is added to a water solution of triethanolamine, an emulsion tends to be formed spontaneously. This method, therefore, consists in simply dissolving in the oil approximately 6 to 20 percent of the fatty acid, which includes any free fatty acid naturally occurring in the oil, and mixing the solution with a 2 to 8 percent solution of triethanolamine in water. This method usually yields a spontaneous emulsion which is converted by moderate agitation into a product of satisfactory stability. If a minimum of the water solution is used, a concentrated emulsion results which is capable of storage indefinitely without separation, and which may be diluted readily with more water when desired for use.

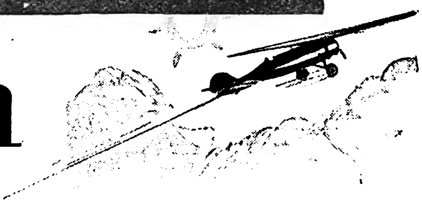
Low-viscosity mineral oils not only can be emulsified by this method, but they can be made up as "soluble oils." There is a wide application for soluble mineral oils. They form the basis for machine cutting oils, for orchard sprays, for polishes, and for a number of textile oils.

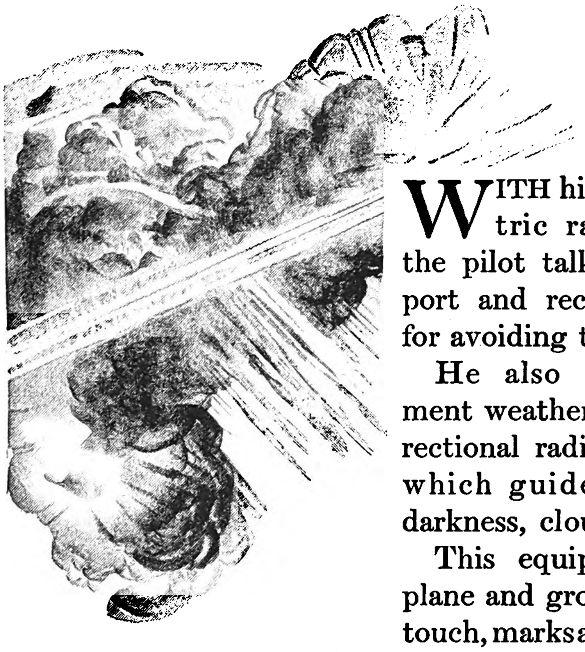
The most interesting field for these oils, perhaps, is in the textile industry. Although mineral oils are theoretically best fitted for textile lubricants, they have hitherto been at a disadvantage due to the great difficulty experienced in removing them completely out of the finished cloth. Oils prepared with triethanolamine overcome this difficulty, and tests have shown that the above soluble oils, even after several weeks of aging in the cloth, are readily emulsified and removed with pure water.

The linseed-oil emulsions offer very interesting applications. Inasmuch as most boiled oils have an appreciable content of free fatty acid, emulsions may be made with the addition of only triethanolamine in the amount of 0.5 percent. Such emulsions, in the water phase, are used as the base for paints that are required to be of exceptionally low fire hazard, and for



Out of the storm





–*by telephone*

With his Western Electric radio telephone the pilot talks with the airport and receives directions for avoiding the storm.

He also hears Government weather reports and directional radio beacon signals which guide him through darkness, clouds or fog.

This equipment, keeping plane and ground in constant touch, marks a great step ahead in flying. It helps to put the new mode of travel on a dependable, efficient basis—doing for air transportation what telegraph, telephone and wireless have done for railroads and steamship lines.

The airplane telephone is backed by more than 50 years' experience with problems of voice transmission.

It was designed by Bell Telephone Laboratories and tested under actual flying conditions in their own planes. It is made with the same care and skill as all the Western Electric apparatus used by the Bell System.

When you travel or ship goods by air, ask whether the plane is equipped with Western Electric Airplane Telephone.

MADE BY
THE MAKERS OF

Aviation Communication Systems

paints, such as are used for lettering asphalt, which must have no solvent effect on the under-surface.

Wax emulsions are finding a growing use due to their increased cheapness and low fire hazard compared with hydrocarbon solutions, especially since coating and polishing operations can be performed practically as readily with either type of dilution. A paraffin emulsion has been applied successfully to the coating of paper, board, and window shades and a carnauba emulsion to leather and linoleum. Together with other constituents they have a wide variety of applications. As an example, the carnauba wax emulsion has been made up with turpentine and nigrosines to give an excellent shoe polish with cleaning, scouring, polishing, and blacking properties.

The kerosene emulsion is especially interesting as a tree-spraying material. It may be made in a very stable form with a concentration of kerosene up to 85 percent of the oil by volume and readily dilutable with water; in this respect, at least, it is far superior to the usual orchard sprays.

Further emulsions which have been made with triethanolamine confirm its general utility in this field. A number of edible oils, such as olive, castor, and refined oils, the palatability of which is greatly increased by emulsification, are readily emulsified with this base, although they may not be recommended for internal use until the physiological inertness of triethanolamine has been confirmed.—*A. E. B.*

Art as Sales Stimulant

THE growing importance of art in commerce as exemplified in the increasing attention on the part of manufacturers to improve the appearance of products was emphasized by the Secretary of Commerce, Robert P. Lamont, in an address before the annual convention of the American Federation of Arts in Washington.

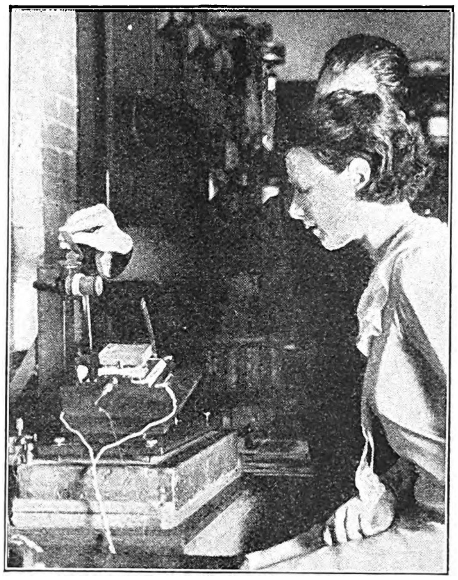
Mr. Lamont said that more and more people are realizing the association of art to everyday life and that this association is manifesting itself in the minds of designers and producers of merchandise. The incorporation of beauty through color and form into the products of our industry should increase the market for our goods.

Measuring the Oilyness of Oil

THE accompanying illustration shows W. C. Wilharm, Research Laboratories, Westinghouse Electric and Manufacturing Company, demonstrating to a visitor the device he has developed for measuring the oilyness of oil.

The device consists of a weighted platform supported by three highly polished steel balls and resting on an equally highly polished steel plate which is covered with a film of oil. The steel balls cut through the fluid film and rest on the tightly absorbed film built up by certain molecules present in the lubricant. The plate is fastened to a hinged platform which is raised slowly by means of the crank which Mr. Wilharm is shown turning in the photograph.

Thus, the angle between the plate and the horizontal is increased gradually until the weighted platform supported by the steel balls moves, slipping over the absorbed film of molecules. The slightest movement of the platform is rendered perceptible by the action of a voltmeter connected in a circuit which is closed when the platform comes in contact with a needle after moving only .001 inch. The tangent of the angle between the plate and the horizontal attained when the platform begins to slide is the coefficient of friction.



Demonstrating a device designed to measure the oilyness of oil

In this way, the device, determining the angle at which the balls will slide over their absorbed film of lubricant molecules, measures the oilyness of the oil. Of course, the smaller this angle, the greater the oilyness and the better the oil for lubrication purposes.

Rural Radios

A RADIO in every country home is the wish of the Virginia commissioner of agriculture, George W. Koiner, as expressed in a statement just issued.

"It is stated that 35 percent of the farmers have radios," Mr. Koiner said. "In some sections there are more than in others. The radio is a great boon to the isolated country home. The best music in the great cities may be brought to the home which could never be heard otherwise. Also the important market news and the interesting sporting news for both the old and the young. We wish there could be a radio in every country home."

Is Private Flying Dangerous?

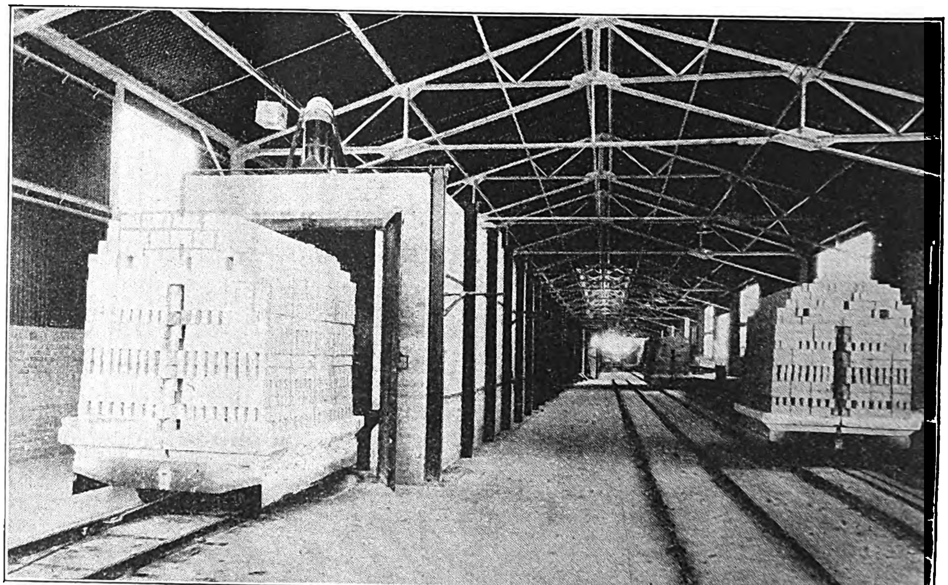
EARLE OVINGTON was the first airmail pilot (1911). He is President of the Early Birdmen, a semi-serious, semi-humorous secret society and he has kept up-to-date by recently securing a transport pilot's license. His views on private flying, as expressed before the Seattle Aeronautical Meeting of the American Society of Mechanical Engineers are therefore, though somewhat pessimistic, worthy of serious consideration.

Mr. Ovington asks "Why are there so few private owners of airplanes?" and continues: "I will answer this question by saying: because the airplane really suitable for the private owner, has yet to make its appearance." Perhaps the readers of these columns will disagree with Mr. Ovington—practical light planes are with us already, in the opinion of many observers.

His views on certain desirable characteristics of the light plane are far less open to controversy.

He would like to have:
Perfect visibility.
The pilot's seat as far as possible from the engine, to minimize crash hazard.
A smooth six-in-line, inverted, air-cooled engine.
A landing speed far lower than that of the conventional airplane of today. A private plane should not land at the speed of an express train.
Perfect stability.
No dangerous stalling.
No noise.

He does not consider less cost im-



Only a few years ago, temperatures of 2800 degrees, Fahrenheit, were believed impossible for tunnel kiln operation in the manufacture of bricks. Progress in the ceramic art, however, has been so great that the gas-fired kiln, shown above, has been developed to a point where it operates continuously at the temperature mentioned, and turns out fire brick for furnace linings at the rate of 12,000 per day. The kiln is 325 feet long and a 100-ton hydraulic pusher moves the flat cars loaded with brick through it

POWERFUL LITTLE DROPS

A GALLON of Ethyl Gasoline contains only about a teaspoonful of Ethyl fluid. Yet these few drops change the action of the fuel entirely when it gets inside the cylinder.

Ethyl fluid is a governor of combustion. With increased compression, the gasoline tends to burn abnormally and the engine "knocks." Ethyl fluid regulates the combustion so that instead of a sharp irregular explosion that *slaps* the piston downward, Ethyl Gasoline burns with slowly gathering force that develops a powerful *thrust.*

That's why Ethyl Gasoline gives so much more power. That's why it develops the maximum efficiency of the new high-compression motors. That's why it stops "knocking" and gets additional power out of every automobile.

Just a few drops of Ethyl fluid, but they are *powerful drops.*

Try Ethyl. Try it on hills, in traffic, under the most trying driving conditions. Ethyl will improve the performance of your car, whatever its size, type or age. Fill up with Ethyl at any pump bearing the emblem shown below. Ethyl Gasoline Corporation, Chrysler Building, New York City.

The active ingredient used in Ethyl fluid is lead.

WITH ETHYL BRAND OF ANTI-KNOCK COMPOUND ETHYL GASOLINE CORPORATION NEW YORK, U.S.A.

Knocks out that knock

Wherever you drive—whatever the oil company's name or brand associated with it—*any* pump bearing the Ethyl emblem represents quality gasoline of high anti-knock rating.

GOOD GASOLINE + ETHYL FLUID = ETHYL GASOLINE

portant. It is more safety that we want.

Mr. Ovington believes that the Curtiss *Tanager*, winner of the Guggenheim Safe-Aircraft competition is a step in the right direction, though far from being an ideal plane.

Comparing the safety of private flying with that of regular air-transport flying, Mr. Ovington gives the transport service the best of the argument:

Two complete sets of instruments and controls are mounted in the cockpits of this new sport trainer

"When you fly on a schedule airline, the circumstances usually are 'right.' The pilot is well trained; his experience has been extensive; the plane is the best obtainable; its mechanical condition is everything that could be desired; the airway is well known to the pilot; emergency landing fields and airports are usually frequent along the route; and undue risk is not usually taken on account of weather conditions.

"In private flying, the pilot often is not well trained; his experience is often inadequate in spite of the fact that he must pass the Department of Commerce tests in order to get his license; his ship, so far as design and construction is concerned, does not always compare favorably with the large air transports, and its mechanical condition is not always perfect; because the private owner does not, as a rule, follow an airway, landing fields and service stations are not always convenient. Only when it comes to weather conditions is the private owner better off than the air-transport pilot; the private owner is usually a fair-weather pilot and largely avoids weather risks."

On the other hand Mr. Ovington has quite a splendid time with his own plane. This veteran pilot paints a glowing and interesting picture, particularly for the man who is mechanically inclined. He does his own servicing, adjusting, and grooming. His airplane is a hobby with him. "I'm never happier than when I'm in my hangar, unless it be when flying my always well-groomed ship."—*A. K.*

Rheumatic Fever

RHEUMATIC fever is responsible for at least one half of all cases of heart disease and the death rate for heart disease in the United States is more than twice that of the second greatest cause of death. For this reason, research on heart disease is attracting more and more investigators throughout the world. Coombs, who has studied the disease extensively in England, is convinced that children acquire rheumatism because defects of inheritance and environment combine to permit invasion of the germs that takes place through the tonsils in at least one third of the cases. Miller of England places special emphasis on the living conditions, finding this disease particularly in poor and damp neighborhoods.

All authorities are agreed that the chief hope of control of these conditions is early recognition and considerable attention to such early signs as pains in the limbs known as "growing pains," slight rise in temperature, and fatigue. Whenever the tonsils are infected, the heart must be examined repeatedly to find out whether or not it is involved in the infection. Miller warns particularly about watching the pale, tired child with poor appetite, who looks feverish and sick and who has a little fever at night.

In view of the lack of knowledge as to the actual cause of this disease and of the way in which children are infected, it becomes obvious that the attack upon it must be made from every possible point of view. In modern research, biology, chemistry, bacteriology, pathology, and all of the other related fundamental medical sciences, are brought to bear in searching for the solution of any disease problem.—*M. F.*

A Neat Sport Trainer

THE aircraft industry is peculiar in that the training of students is one of its most important activities. But some day flying will become so easy to learn that airplane trainers will disappear. For the present, however, the number of training planes built per year equals, if it does not exceed, the number of all other airplane types. However, as flying becomes gradually a private owner's affair, the attempt is made by dsigners to combine the functions of a trainer with that of a sport machine. Hence the name "Sport Trainer" for the new two-seater biplane built by the Verville Aircraft Company. It is an excellent example of what our manufacturers can do at their best.

In the matter of equipment, for example, much more is available now than in the early days of cockpits empty of everything but seat, control wheel, and rudder bar.

The Sport Trainer calls for the following accessories: standard steel propeller; Heywood air starter; balloon wheels; dual A. P. C. brakes; oildraulic shock absorbers; fully castorable tail wheel; dual stick control; parachute seats; head-rest; two 3-piece safety glass windshields; gasoline gage; tool compartment and kit; air speed indicator; two tachometers; compass; two altimeters; two oil pressure-gages; navigation lights; dry battery; fire extinguisher; first aid kit; dual throttles; dual switches; dual stabilizer adjustment; and baggage compartment. The brakes can be controlled from either cockpit, separately or simultaneously.

The reader will note the repetition of the word dual. For many years there was a controversy as to the installation of instruments in a training plane. Designers argued that the same instruments should be seen by both instructor and student, and that the student did not need to have all controls under his command at the start. This resulted in peculiar arrangements of the instrument board. So that both occupants could see them, they were sometimes mounted on the trailing edge of the upper wing, sometimes at the side of the fuselage, and in other unlikely locations. With improvement in instrument construction, so that two sets of instruments can be relied upon to read exactly alike, duality has apparently won out.

The specifications of the Trainer are as follows: Span, 31 feet; length over-all, 24 feet 3½ inches; height over-all, 8 feet 9 inches; power plant, Continental A-70, 165 horsepower at 2000 revolutions per minute; fuel capacity, 36 gallons; fuel consumption at crusing speed 9 gallons; normal range, 328 miles; wing loading, 9.27 pounds per square foot; power loading, 13.6 pounds per horsepower; pay load, 420 pounds; weight empty, 1562 pounds; gross weight, 2243 pounds; high speed, 115 miles per hour; climb, 900 feet per minute; cruising speed, 95 miles per hour.

The arrangement of the cockpits in a training plane is most important. There should be good vision forward and down. It should be easily possible to make a parachute jump from either cockpit. If our reader will imagine himself seated in either cockpit, he will see that both objectives are attained. There should be,

Giants out of the earth

An Advertisement of the American Telephone and Telegraph Company

No AGE but ours has seen so swift and complete an application of natural forces to the doing of daily tasks. Man's leaping knowledge . . . embodied in industrial plants and laboratories, airplanes and electric locomotives . . . has won new power and freedom. Machines are the symbols of a new relationship with nature. They are the servants of this civilization . . . helping men to extend the limits of their opportunities, to change the character of their life.

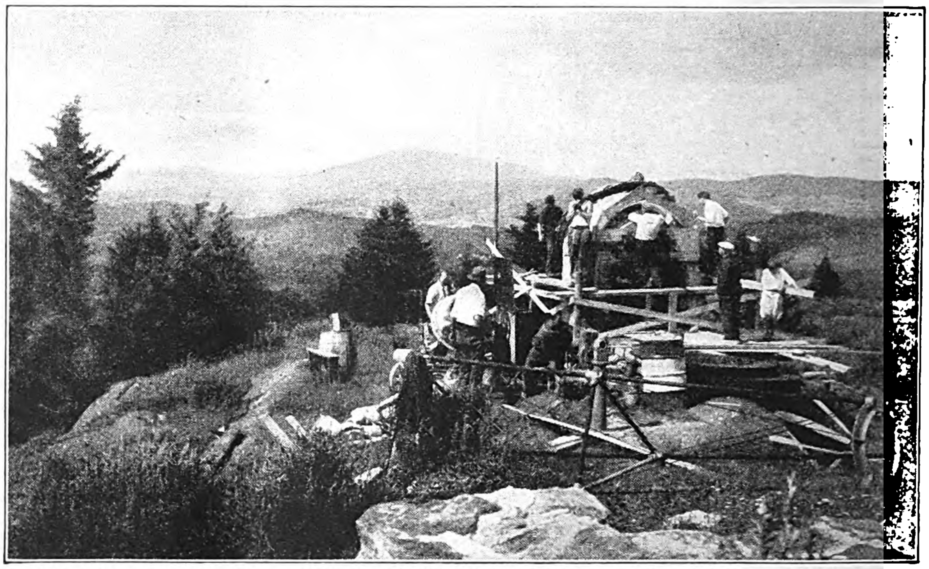
Americans have been pre-eminent in this change, for in whatever they do they seek to utilize nature to the utmost. They have taken the power out of the earth and from the running streams. They have made it turn the wheels of their industry and move their products by rail and road. They have made color and variety out of chemistry. They have spun metal in slim wires to carry their voices anywhere with the speed of light . . . and make neighbors of the scattered millions of America.

Joining homes and work places, towns and distant cities, the Bell Telephone System has furnished a new communication for this new age. Forwarding the growth of the nation, giving better and more complete service in advance of the demand, its function has become the indispensable one of furnishing the means of social and business contacts in crowded cities and scattered villages over the length and breadth of a continent.

The Bell System is constantly improving the scope, speed and accuracy of its service. Its work of contributing to the welfare and prosperity of American life goes on with increasing purpose and pace.

The Amateur Astronomer

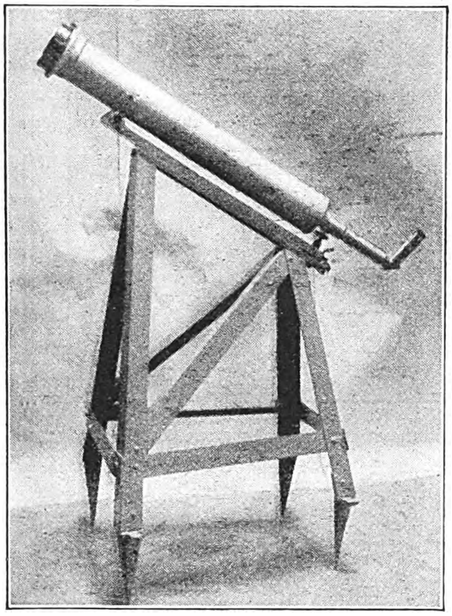
Conducted by ALBERT G. INGALLS



The Telescope Makers of Springfield erecting the new Porter turret telescope

JOHN M. PIERCE, President of the "Telescope Makers of Springfield" (Vermont) estimates that 2000 telescopes actually have been made since 1926 when this journal opened its amateur telescope making campaign. That figures about 30 percent of those who have obtained the SCIENTIFIC AMERICAN instruction book "Amateur Telescope Making" and is a good showing when the unusually exacting nature of this work is considered.

Telescope making is not a hobby which is likely to appeal to the masses; it is a little too stiff for them. It recently was tried on the readers of several newspapers, who were given a syndicated series of simple "how-to-make" instructions for a reflector. The results, to put it mildly, were nothing to shout about. (Recently, by the way, we stated in these columns that amateur telescope making was too stiff for boys as well as average newspaper readers and several of our readers took the word boys to connote all minors. Perhaps "kids" was the intended word. One might say the dividing line between the "too-stiff-fors" and the "not-too-stiff-fors" is plane geometry. If a lad has studied geometry, nothing in the amateur telescope making hobby should stump him, other things being equal—namely that he be fairly handy and a bit more "stick-to-it-ive" than the average lad.)

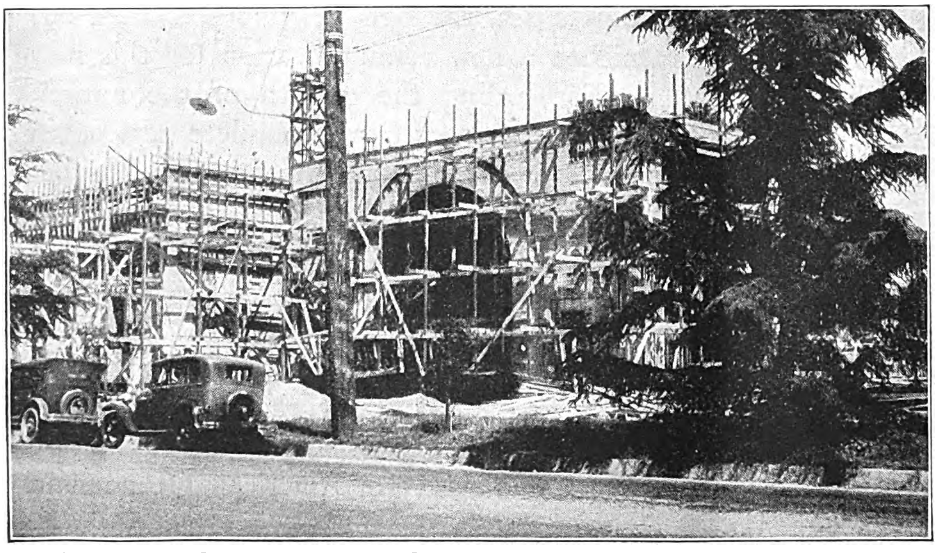


One of the six 4-inch refractors designed by Porter for use on *Polaris* to study "seeing" by Anderson's method at several sites in California and Arizona with a view to selecting a suitable location for the 200-inch telescope. Two larger telescopes will be used in the final tests at a later date

Another gratifying evidence of the consistent, even if not meteoric, spread of the amateur astronomical and telescope making hobby was the attendance at the yearly "get-together" of the worst addicts—the flea-bitten regulars who take telescope making instead of their meals—held last month at "Stellafane," near Springfield, in the hills of southeastern Vermont. As these words are written (in a jiggling Pullman berth) the fifth of these annual conclaves is just over and, despite the frowns of bad weather, more visiting fans from neighboring states attended than on any of the previous occasions. Running down the list of registrants one sees a well scattered following, as connoted by their home towns, Newport, New London, Boston, Pittsfield, Brookline—all places in nearby New England; also New York, Princeton, Philadelphia, Rochester, Pittsburgh, and Detroit. A special contingent came from Pittsburgh, representing the thriving association of amateur telescope makers recently organized there.

As usual there was a Saturday evening "feed," although the time-hallowed "piece of resistance," real beanhole beans, did not materialize. The evening meal stowed away, the assembled enthusiasts listened to a talk by Russell W. Porter, Associate in Optics and Instrument Design on the staff of the California Institute of Technology. Mr. Porter spoke on, or rather "around," the subject of the great 200-inch telescope. Nearly all the extant plans are tentative and therefore little of a definite nature may be told about them as yet. We reproduce two photographs showing the first tangible beginnings, but the mammoth telescope doubtless will be many years in the making.

The small testing telescope shown is equipped with gooseneck prism and an eyepiece which is essentially a compound microscope giving a magnification of 7500 diameters. The quality of seeing afforded at a number of sites which are under careful investigation is determined by ascertaining the number of diffraction rings visible around the central disk of a star and how much the image of a star shifts, in terms of its diameter, when local atmospheric disturbances affect it. The



Through this large, arched portal adjoining the new instrument shop of the California Institute of Technology will go the 200-inch mirror blank to be ground and polished in the large optical shop to be built later to the right

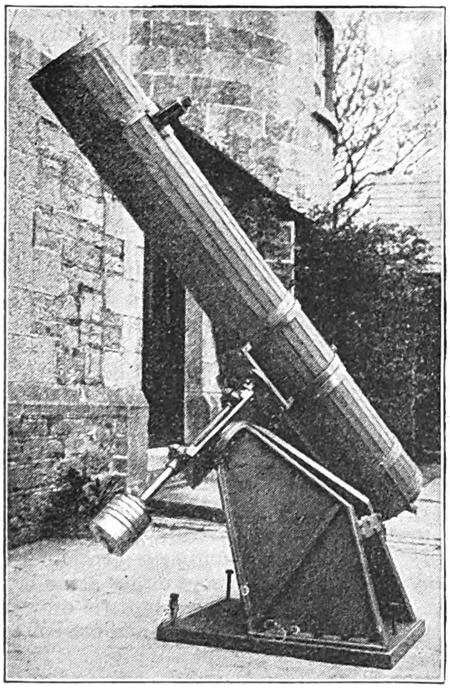
star *Polaris* is the test star. Any other star would suffice, but careful study of the picture will show that the telescopes were designed especially for use on *Polaris* because that star remains for all practical purposes at the same place all night—in other words the use of *Polaris* is a matter of convenience.

As other new facts concerning progress on the 200-inch telescope become available for publication this journal will endeavor to report them.

The telescope enthusiasts, convened at "Stellafane," obtained a glimpse of the new Porter turret telescope—"new" only because recently set up (see one of the illustrations, which shows the work in progress just before the meeting; also see "Amateur Telescope Making," second edition, page 51, illustration at VI). We hope to publish a picture in a later issue, showing the complete mounting.

The turret, made of concrete, will house two telescopes, the larger one a Porter combination having a 16-inch paraboloid and a 16-inch flat, focal ratio *f* 13; the smaller one a 12-inch Cassegrainian with *e. f. l.* of 4 on 4, or *f* 16. The rings of the turret are of iron and have an external diameter of seven feet; they show toward the lower right. In the foreground is the long arm, made of tubing, to carry the 16-inch paraboloidal mirror. It, with the iron ring, dome, and counterwieight, will weigh about 4000 pounds.

The picture shows "the boys" at work erecting the telescope. Porter, the gang boss, is the figure with the long stogie; the rest are working—especially Pierce, whose hat alone is visible (on the skyline) while he compacts the concrete in the forms with his feet. The photograph was taken by Oscar S. Marshall. In the background is Ascutney Mountain. Next year when you come to the Sixth Annual Astronomical Riot at "Stellafane" the new Porter turret telescope will be ready for you to use.



An 8½-inch reflector recently built for Senor Jose Fernandez of Argentina, by the Reverend Mr. W. A. Ellison of Armagh Observatory, who did not send further description. The roof of Ellison's stone workshop shows at right

COLUMBIA UNIVERSITY
HOME STUDY COURSES

Are Your Opportunities Slipping By?

The years roll by faster and faster seemingly. More and more frequently come those moments when we regret the opportunities we allowed to slip by. When we realize that we have made little or no progress; that we have acquired no new mental equipment, and no increased capacity for business or social life. . . . You must *do* something if you expect to accomplish anything worth while. But you will need perseverance and study. . . . Columbia University, as one of the world's leading educational institutions, urges you to use part of your time in study. Not solely for the attainment of greater efficiency in business, but for a fuller social life, and for the real joy of having a more intelligent point of view. Whatever your objectives may be, and wherever you live, splendid studies that lead to these objectives are available through Columbia Home Study Department. The range of subjects is wide.

+ + +

These courses have been prepared by our instructors to meet the special requirements of study at home. While all basic material essential to the full understanding of each subject is fully covered, sufficient elasticity is allowed to permit adaptation to the individual needs of the student. Every one who enrolls for a Columbia course is personally taught by a member of the University teaching staff. Special arrangements can be made for group study.

The University will send on request full information about these home study courses. A coupon is printed below for your convenience. If you care to write a letter briefly outlining your educational interests our instructors may be able to offer helpful suggestions. Mention subjects which are of interest to you, even if they are not listed here, as additions to the courses offered are made from time to time.

High School and College Preparatory Courses

Columbia University Home Study Department has prepared courses covering the equivalent of four years of High School study. This complete High School or College Preparatory training is available to those who can not undertake class room work. We shall be glad to send you our special bulletin upon request.

Current Bulletin Briefs

Short Reviews of Bulletins and Papers on Scientific and Allied Subjects, and Where to Get Them

Bibliography of Aeronautics, 1928, gives the information in dictionary form with author and subject entry and one alphabetical arrangement. Citations of the publications of all nations are included in the language in which these publications originally appeared. *Superintendent of Documents, Washington, D. C.—50 cents (money order).*

Instructions for Installation and Care of Brown Electric Flow Meters (Instruction Book 214). The flow meter is an instrument of precision and must be treated as such; this book tells how. *The Brown Instrument Co. of Philadelphia, Pa.—Gratis.*

Bearing Value of Soils—Foundation Engineering deals with soil pressure, soil character, soils under load, soil tests, examples of failures, and so forth. The paper was prepared by C. C. Whittier. *Robert W. Hunt Company, 2200 Insurance Exchange, Chicago, Ill.—Gratis.*

European Motion Picture Industry (Trade Information Bulletin No. 694, United States Department of Commerce) gives up-to-date information such as the fact that at the end of 1929 there were 1670 European motion-picture houses wired for sound films. Continental film leaders now regard the soundfilm as the entertainment of the future and the multilingual feature as a necessity for foreign trade. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

The Bowie Method of Triangulation Adjustment in the First Order Net in the Western Part of the United States (Special Publication No. 159, Coast and Geodetic Survey, U. S. Department of Commerce) by Oscar S. Adams, Senior Mathematician. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Fertilization of Shade Trees (Bulletin No. 1, June 1930, Research Department, The Davy Tree Expert Co.) deals with the advisability of chemical fertilizers for conifers. *The Davy Tree Expert Company, Kent, Ohio.—Gratis.*

A New Method of Evaluating the Potency of Antineuritic Concentrates. (Reprint No. 1348 from the Public Health Reports), by Maurice I. Smith. A study in the chemistry of the antineuritic vitamin. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

Preventing Cracks in New Wood Floors (Leaflet No. 56, U. S. Department of Agriculture) by L. V. Teesdale, Senior Engineer, Forest Products Laboratory, Madison, Wis., gives valuable information as to cause and prevention of floor cracks. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

Sectional Map Indicating Main Automobile Roads Between Canada and the United States is divided into four sheets—Atlantic, Great Lakes, Middle West, and Pacific sheets. When ordering, indicate in which section you are interested. *Address F. C. C. Lynch, Director, Natural Resources Intelligence Service, Ottawa, Canada.—Gratis*

The Killifer Tillage System is a valuable, fully illustrated treatise on a system of soil tillage. *Killifer Manufacturing Co., 5525 Downey Road, Los Angeles, Cal.—Gratis.*

Museums, a Magazine Popularizing Museums. Edited by Ralph Clifton Smith, *Editorial Office, 3732 Van Ness St., Washington, D. C. $3.00 a year, single numbers 25 cents.*

Geology of the Eagle-Circle District, Alaska (Geological Survey Bulletin 816, Department of the Interior) by J. B. Mertie, Jr. *Superintendent of Documents, Washington, D. C.—50 cents (money order).*

Borate Mineral from the Kramer District Mohave Desert, California (Professional Paper 158-I., Geological Survey, Department of the Interior) by Waldemar T. Schaller. *Superintendent of Documents, Washington, D. C.—20 cents (coin or money order).*

Review of Legal Education in the United States and Canada for the Year 1929 by Alfred Z. Reed deals with the missing element in legal education, practical training, and ethical standards. *The Carnegie Foundation for the Advancement of Teaching, 522 Fifth Ave., New York City.—Gratis.*

Beginning the Second Century is a piece of institutional literature produced in celebration of the centennial anniversary of the invention of the platform scale by Thaddeus Fairbanks, and the founding of the company which bears his name. It is beautifully illustrated. *Fairbanks, Morse & Co., Publicity Department, 900 South Wabash Ave., Chicago, Ill.—Gratis.*

Hickory Golf Shafts (Commercial Standard CS18-29, Bureau of Standards, U. S. Department of Commerce) gives full diagrams. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

Tractor Lubrication is the title of a little monograph which shows that power economy is the ultimate objective in tractor lubrication.—*The Texas Company, 135 East 42nd St., New York City.—Gratis.*

Personnel Research Agencies (Bulletin of the United States Bureau of Labor Statistics No. 518) has been prepared by Estelle M. Stewart of the United States Department of Labor. It is a most valuable pamphlet of over 200 pages dealing briefly with such subjects as employment management, industrial relations, employment, safety, hygiene, cost of living, et cetera. *Superintendent of Documents, Washington, D. C.—35 cents (money order).*

Foreign Students and the Immigration Laws of the United States. (Bulletin No. 1, Institute of International Education) by Ruth Crawford Mitchell is a monograph on a subject on which it is rather difficult to obtain dependable information. Two editions have been called for in 1930. *Institute of International Education, Inc., 2 West 45th St., New York City.—25 cents.*

Ethnology of the Mayas of Southern and Central British Honduras (Publication 274, Anthropological Series, Vol. XVII. No. 2) by J. Eric Thompson, Assistant Curator of Central and South American Archelogy, Field Museum of Natural History. Here we have detailed anthropological studies of some of the living descendents of the ancient Mayas written in most interesting style. *Field Museum of Natural History, Chicago, Illinois.—$3.00 plus postage.*

Design for Kansas Farm Homes (Kansas State Agricultural College Bulletin, Vol. XIII. No. 10) by H. E. Wichers, is a publication (Bulletin 23) of the Engineering Experiment Station. The 102 page pamphlet gives 38 designs for houses accompanied by floor plans. It is a valuable contribution to the small home literature.—*Engineering Experiment Station, Kansas State Agricultural College, Manhattan, Kansas.—Gratis.*

Principles and Operation of Pioneer Instruments is a pamphlet containing many diagrams and is sold either alone or with a set of enlarged diagrammatic drawings which are 17 x 22 inches and are suitable for classroom or lecture use. The "manual" contains reduced copies of the diagrammatic drawings with accompanying text. *Pioneer Instrument Company, 754 Lexington Ave., Brooklyn, N. Y.—Diagrammatic Drawings and the Manual $2.50; Diagrammatic drawings only, $2.00; Manual only 75 cents.*

The Scientific American Digest

(*Continued from page* 318)

and is, a neat, heavy cowling for the front end of the fuselage. The exhaust ring and the engine as a whole should blend gracefully into the fuselage, and they do. The landing gear should have a wide tread and be rugged, and it is. The landing gear should absorb shocks readily, and it does, since it is provided with both oildraulic shock absorbers and air wheels. It should be easy to take the upper wing down, and since it is in one piece, this is easily accomplished. There should be a handy catwalk on the lower wing on either side of the fuselage, and there is.—*A. K.*

New Fertilizer Reported

A NEW phospho-nitrogen fertilizer, obtained from a base of natural phosphates, is reported by the United States Assistant Trade Commissioner in Paris, to have been perfected by a French engineer, a technical director of one of the Algerian mining companies. Natural phosphates are treated with hydrochloric acid in the proportion of one to one. Ammonium sulfate is then added to the clear solution, the mixture filtered in order to eliminate the precipitated calcium sulfate, and calcium carbonate is then added to the filtrate. The fertilizer manufactured in this manner contains 18 percent phosphoric acid, soluble in citrate, and 14½ percent of ammoniacal nitrogen.—*A. E. B.*

Salt of the Earth Made to Fit Varied Needs

THERE is a silver thread of salt closely woven into the fabric of all human history, says Dorothy Robinson in a recent issue of *Food Industries*. It is doubtful if any commodity has had a greater effect upon the history and civilization of the peoples of the earth. Its value from ancient times is most clearly indicated, perhaps, by the prominence salt has occupied, not only in commerce but in religious and moral development. Invariably it was used in religious rites as a worthy offering, and every language has its common sayings concerning the welding of bonds of friendship through the eating of salt. Such a one is the Arab phrase "There is salt between us."

The modern salt plant, such as the one at Manistee, Michigan, described by Miss Robinson, is located over the vast underground deposits of rock salt. A pipe is sunk 2000 feet below ground and through it water is sent down to dissolve the salt. The salt solution is then pumped up into huge wooden settling tanks where some of the impurities settle out. The salt solution is then evaporated, either slowly in open vats called "grainers," or rapidly in steam heated vaccum pans. The product of the grainer is a flake salt whereas the vacuum pan produces a granular salt. The salt thus crystallized is dried and screened to obtain the many varied grades demanded by different users.

Butter makers must have a small, soft-flake salt of high purity; the cheese manufacturers desire a similar salt but of coarser grain; the canners demand a fine granulated salt to maintain color and freshness in their products; the flour manufacturers mix an exceptionally fine salt with prepared

WANTED MEN

To Manufacture Metal Toys and Novelties

Big demand for Toy Soldiers, Animals, 5 and 10c Store Novelties, Ashtrays; etc. We co-operate in selling goods you make also buy them from you. Small investment needed to start and we help you build up. WE FURNISH COMPLETE OUTFITS and start you in well paying business. Absolutely NO EXPERIENCE and no special place needed. A chance of a lifetime for man with small capital. CHRISTMAS RUSH is now starting, so if you mean strictly business and want to handle wholesale orders now being placed write AT ONCE for full information.

METAL CAST PRODUCTS COMPANY

1696 Boston Road Dept. S New York City

Business Opportunity

MANUFACTURER HIGHEST GRADE ELECTRICAL and radio products with international sales organization desires to diversify its products by (1) acquiring an established article in need of financing and sales effort, (2) manufacturing and selling new articles. Give detailed information. Principals only.

Box 199, SCIENTIFIC AMERICAN

SPRINGFIELD RIFLE, MODEL 1903

CAL. 30, REDUCED TO $16.50

8¾ pounds, 43 inches long, 24-inch barrel, offered assembled and refinished, without bayonet at reduced price, $16.50. Ball cartridges $3.50 per 100. Illustrated catalog, 380 pages, Army-Navy equipment, mailed for 50 cents. NEW circular for 2c stamp. Established 1865.

flour. The meat packers in Chicago alone, last year, used 500,000 tons of coarse flake salt in curing and preserving meat. In other words, each manufacturer must have a salt which is adapted for his purpose, and by varying treatment of brine, methods of manufacture, drying, and screening, all of these demands can be supplied.

Even the farmer has salt put up especially for his use. Fifty-pound lots of granulated salt are dried and pressed in a large hydraulic press at 1000 tons per square inch pressure into a salt block to be used as a salt lick for cattle. For table salt, 1 percent of filler is mixed with the salt to prevent absorption of moisture and consequent hardening. For the much-advertised iodized salt, 0.02 percent of potassium iodide is added, as iodine compounds are an aid to health in the prevention of goiter.—*A. E. B.*

Alcohol As Motor Fuel

EFFORTS of the Brazilian government to popularize use of alcohol motor fuel are meeting with success, according to reports to the Department of Commerce by Assistant Trade Commissioner J. Winsor Ives, Rio de Janeiro.

Official cars are required to use this fuel and 60 percent of all cars in Pernambuco are regular consumers.

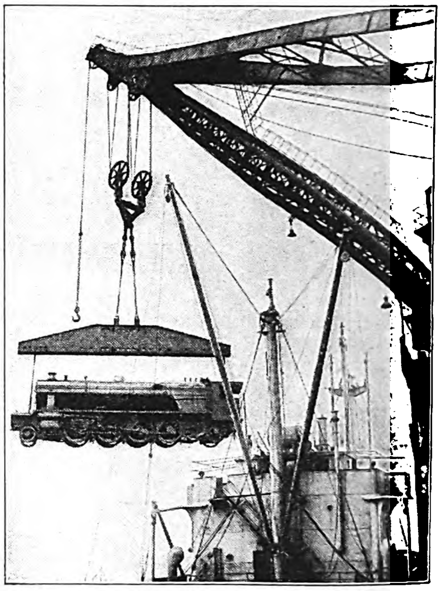
Petroleum companies maintaining branches in Pernambuco report reduced sales of gasoline due to the lower price of alcohol fuel. Alcohol motor fuel, which consists of a mixture of cane alcohol and ether, is selling from 500 to 700 reis (approximately six to eight cents) per liter, with gasoline approximately 18 cents.

Proprietary and Medicinal Foods

THE old time tonic and patent medicine has given way to the stimulating food. Years ago everyone who became depressed or fatigued or disabled in general, thought he ought to have something from a bottle to give him back the vim, vigor, and vitality that he had lost. The Food and Drugs Act and the publicity which followed its passage have made people realize the preposterousness of this belief. The newer knowledge of the vitamin has, however, brought into the situation the attempt to replace the old time products by new combinations of vitamin foods. The food faker, as has been pointed out by Dr. W. McKim Marriott, follows closely behind the investigator of nutrition, picks out an occasional truth, and distorts and broadcasts it to the unsuspecting public. Diabetic foods, pre-digested foods, and brain foods are sold with claims that are preposterous—are sold indeed with the impression that it is possible for the food to depart from the stomach and go immediately to the one portion of the body to which it may be aimed. All of the foods are reduced in the digestive tract to elemental substances, resynthesized into products that can be taken up by the blood and then distributed generally to the various parts of the body.

In addition to special foods for special portions of the body, there are products sold with a vaunting of the claims of calcium, iron, phosphorus, iodine, and all of the alphabetical vitamins. Claims are made again and again for special virtues associated with the use of certain food substances, before scientific research definitely has established the fact that the claims are warranted. Because a fresh product contains vitamins, it can not be assumed that the preserved product has retained the vitamins.

Perhaps one of the most significant phases of modern research in the canning field has been the attempt to substitute exact knowledge for guessing in the promotion of the canned food. Already it is known through research conducted in your own "laboratories" that the sun ripened tomato is much more likely to be an adequate source of vitamin C than the green product hastily ripened by artificial means. It is known that American canned tomatoes are likely to contain much more vitamins than English canned tomatoes. Because exposure to the sun's rays produce vitamin D in the body, it can not be assumed that exposure to the sun's rays or to artificial ultra-violet will produce vitamin D in every other living tissue. Unless a sufficient quantity of ergosterol, the precursor of vitamin D, is present in the tissue, exposure to ultra-violet rays will not produce the vitamin.



Although it weighs 119 tons, this locomotive is lifted like a toy to the deck of the S. S. *Belhor* by a huge 150-ton crane. The engine is destined for a railroad in India

It is also important to remember that foods must be taken into the body primarily for growth and health and not primarily for the control of disease. True, the degenerative diseases which afflict mankind are the effects of wear and tear and may be minimized by suitable control of the diet; true, the diseases due to defects of nutrition and the lack of the necessary food substances may be controlled by the provision of the missing vitamins, but in the vast majority of cases mankind eats in order to provide his body with fuel for his energy consumption and to maintain his tissues in a state of health.

Hence the folly of claiming for various natural foods special contents of infinitesimal quantities of various mineral salts and vitamins must not be permitted to dominate the manufacture of millions of cans of staple foods, of millions of packages of cereals, and of millions of pounds of meat. The statement is particularly apropos in connection with recent campaigns asserting the special value of canned foods prepared from fruits and vegetables grown in soils especially rich in iodine or iron or other mineral salts. The quantity of iron or iodine or calcium or phosphorus required by the human body is now definitely known, and it is understood among scientific nutritionists that these quantities are to be had through a vast variety of foods and that a person who eats a well balanced diet is likely to get these quantities without paying special attention to any one of these particular salts. There is no necessity for limiting the output of canned fruits and vegetables to any particular portion of the United States. Wherever these products grow in quantities and in a quality suitable for preservation, they may well be packed for preserving as part of the American diet in a season and at a time when the fresh fruits are not generally available.—*M. F.*

New Finish for Aluminum

A NEW, simple, and cheap method of giving aluminum a dead white finish was described by Leon McCulloch, research chemist of the Westinghouse Electric and Manufacturing Company, in a report to the American Electro-chemical Society. The metal is boiled in milk of lime to which a little calcium sulfate is added. The new coating will be tested as a base upon which to apply paints and enamels to aluminum.—*Science Service.*

Sand as Source of Helium for Airships

MONAZITE sand, source of thoria from which gas mantles are made, may provide the lifting power for future British airships. Work at the Chemical Research Laboratory at Teddington by R. Taylor has shown that this sand is a possible source of helium, the non-inflammable gas that replaces hydrogen in American airships. The United States now has a practical monopoly of helium which is found in extractable quantities only in the natural gas of certain American gas wells. Large quantities of monazite sand are available in the British Empire, especially Ceylon and Travancore, India.

The natural gas from Texas contains about 1 percent of helium, while the monazite sand yields about one cubic centimeter of helium to every gram of sand. This means that to fill a ship of 5,000,000 cubic feet capacity, the size of the *R-100*, newest of British dirigibles, 150,000 tons of sand would have to be refined. The gas escapes from the sand on heating, so in treating it for the manufacture of thoria, large quantities of helium are wasted. In the process for its refinement worked out by Mr. Taylor, the gas is treated with heated magnesium metal which removes most of the nitrogen, and then final treatment with heated calcium removes the rest of the nitrogen and other gaseous impurities—*Science Service.*

Chemist Peers into Atoms With Aid of X Rays

IT is just 35 years since Roentgen discovered X rays. The application of his discovery during that time to medical diagnosis has been of inestimable value to mankind. But there is another, more recently discovered, field of usefulness for the X ray, namely the exploration of the atomic structure of matter. By the use of X rays, the scientist is permitted to "look" down into the fine structure of matter far beyond the power of any microscope. On the 35th anniversary of Roentgen's discovery, the foremost explorer of these hitherto hidden realms, Dr. George L. Clark of the University of Illinois, itemized, in *Chemical Markets*, some of the wonderful recent applications of the X ray diffraction method to industrial problems:

1: Numerous determinations of proper heat treatment of metals. In one case, the X-ray results showed that at the correct temperature for annealing of cast steel parts a better structure was obtained in 30 minutes than in the six hours previously taken.

2: An improvement in the transparency of waxed paper from 40 percent that of air to over 80 percent by a simple application of the diffraction results to influences affecting the crystallization of paraffin wax.

3: A genuine improvement in the quality of rayon by fundamentally showing the structural effect of every step in the process and of adapting these to produce the necessary ultimate structure, or diffraction pattern, essential for proper tensile strength, extensibility, gloss, and so forth.

4: A method of specification for asbestos (single pattern) by comparison with standard patterns associated with practical behavior.

5: Control of addition of dyes and other agents to rubber, and of the primary effects of various treatments on colloidal size—the only method of ascertaining true reproduction of natural rubber in synthetic rubbers.

6: Measurement of particle size in paint pigments, and control of production of carbon blacks.

7: The only exact method of analysis of any material to prove whether or not it is true cellulose.

8: Measurement of film thickness of every kind.

9: Determination of proper conditions for manufacture of best quality of ice-cream, as to size and distribution of ice crystals.

10: Classification and identification of precious and semi-precious stones and routine method of differentiation between fine and cultivated—containing mother-of-pearl center—pearls.

These are but a very few of the remarkable achievements of the X ray when used for the study of atomic structure. So delicate is the diffraction method that the mine from which a sample of asbestos was taken is established by its X-ray photograph, as is the exact age of a growing cotton fiber or the exact process by which a rayon thread had been manufactured.—*A. E. B.*

A Rigging Handbook

SAFETY in flying depends in a large measure on plane maintenance, and this in turn depends on the skill and knowledge of the airplane mechanic. Few American books have dealt especially with the subject of airplane rigging, and we therefore welcome the "Airplane Mechanics Rigging Handbook" by Lieutenant Colonel Rutherford S. Hartz and Lieutenant Elzor E. Hall. It covers the rigging of the modern airplane in clear and simple language, is splendidly illustrated, and is written by men thoroughly conversant with their subject. In addition to covering

Hotels that keep ahead of your demands

The traveling public didn't demand a bath with *every* room, or circulating ice water, or a morning paper under the door at no cost—*until* Hotels Statler inaugurated these things.

There are also bed-head reading lamps, full-length mirrors, colorful furnishings, even threaded needles in the pincushions in every room.

In restaurants there is the widest variety, ranging from formal a la carte service to lunchroom or cafeterias.

But it is in Statler Service that this policy of keeping ahead of your demands is most noticeable. Statler employees are not only instructed but are *trained* in courtesy and helpfulness. They, too, keep ahead of your demands.

MAKE YOUR INVENTIONS PAY

Millions have been made from ideas properly developed and protected by inventors. One of the first steps is the development of a practical working model. Send us rough sketch or model of your idea. We will submit complete report backed by 30 years experience in model making. Confidential service. Modern equipment. Bank references furnished. FREE booklet "Making Inventions Pay."

CRESCENT TOOL COMPANY, Dept. H, Cincinnati, Ohio

I SELL PATENTS

If you wish to add New Products to your line, or have a good Patent to sell, write me—

CHARLES A. SCOTT
Established 1900
773 SA Garson Ave. Rochester, N. Y.

INVENTION FOR SALE

RE-IGNITION DEVICE representing an inexpensive attachment for relighting a gas range burner in the event the same is accidentally extinguished. Will sell outright or on a royalty basis. Address PETER V. GIOE, 343-83rd Street, Brooklyn, N. Y.

Patent Attorney Wanted

A Consulting Engineer, who has had over 20 years' experience in designing and patenting mechanical and electrical devices of all kinds, is expert in detecting loopholes in patent applications and in patents already issued and is very adept in avoiding existing patents, desires to form partnership with high grade patent attorney or a connection with a firm of attorneys already established.

Address Box 200 Scientific American

WANTED INVENTIONS AND NEW PRODUCTS

Prominent manufacturer is seeking worthwhile products to add to his line. Mechanical equipment preferred, but will consider any article having good sales possibilities. Address Box 198, SCIENTIFIC AMERICAN, New York City giving full details.

INVENTOR'S UNIVERSAL EDUCATOR:

Contains 900 mechanical movements; 50 Perpetual Motions; instruction on procuring and selling patents and selecting an attorney, etc. Suggests new ideas. Price $1.00 postpaid in U. S. A. Address Dieterich Company, Publishers, 602H Ouray Building, Washington, D. C.

rigging and inspection, the handbook provides a compendium of practical information on aircraft materials, wood and glue, metal airplane parts, wires, dopes, fabrics, and so forth. The care of parachutes forms a useful concluding chapter.—*A. K.*

Visualizing the Kidney

ONE of the most valuable procedures used in scientific medicine for the study of disease is the method known as "cystoscopy," whereby a tube is introduced into the bladder and the interior of the bladder studied thoroughly. In addition, it is possible to inject substances into the bladder which are opaque to the X ray and thereafter, by means of the X ray, to study the outlines of the organ.

A general examination of the kidneys is an exceedingly difficult matter. The kidneys are connected to the bladder by two tubes called the ureters and the introduction of catheters into the ureters and then to the kidney is an exceedingly painful and difficult task. It has also been necessary, if one wished to take suitable X-ray pictures of the kidneys, to inject a substance into the kidney by means of the tube introduced first into the bladder and then by the catheter into the ureter.

Several years ago Dr. Evarts Graham and his colleagues in Washington University, St. Louis, developed a dye substance which could be injected into a vein and which would then localize in the gall bladder. By this means it became possible by use of the X ray to visualize the appearance of the gall bladder. Attempts have been made over a number of years to develop a similar method for visualizing the kidney, but until recently without success. Such a method is now being discussed in medical periodicals and apparently the goal has been reached. The dye substance used is a derivative of iodine and pyrridone. The substance finally used has been developed after a dozen or more similar substances were used and discarded because of unfavorable side effects.

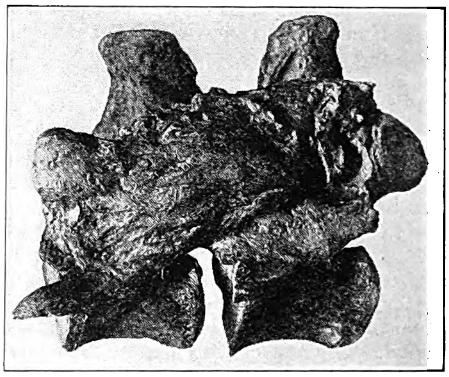
The final product, when injected into a vein, apparently is excreted in the kidney and an X-ray picture will reveal the outline of the organ. By its use in several hundreds of cases, it has been possible to diagnose the presence of cancers or tumors of the kidney, unusual formations of the kidney such as contractions or dilatations, or horseshoe shapes, and the presence of stones and other abnormalities. The method will, no doubt, make it possible, when it is fully developed, for the average practitioner to increase the certainty of his diagnosis. It will also be possible in many instances to avoid the necessity for the more complicated and difficult procedure known as cystoscopy and ureteral catheterization.—*M. F.*

Commercial and Financial Aspects of Aviation

AVIATION has gone through a tremendous boom and is now suffering an equally severe depression, at least from a financial point of view. The thousands of investors in aviation securities are seriously worried. Since knowledge is the best guide to investment or liquidation of investment, we recommend R. R. Bennett's book "Aviation, Its Commercial and Financial Aspects," to all those interested in these phases of this new industry. Published by the Ronald Press, New York City, and written by a man who has made his mark in newspaper writing on aviation, the book discusses the following subjects: The Present Status of Aviation; Safety and Dependability; Financial Aspects; Manufacture of Aircraft; Air Transportation; Airports; Aids to Navigation.—*A. K.*

Stiff Back in the Saber-tooth

THE saber-tooth, dreaded by our cave-dwelling forbears, had a stiff back as shown in the accompanying illustration of two backbone joints which are joined by a heavy bridge of bone brought on by disease or injury. Among the thousands of skeletons of the saber-tooth found in asphalt pits at Los Angeles, California, there are many which show the effects of disease, a study of which sheds light on the nature of ancient maladies. The one pictured here recalls a human disease in which the muscle of a part turns to bone, a disease which the doctors call *Myositis*. In some cases the backbone is completely solid for a distance of several inches.



The bridge of bone found on the backbone joints of a saber-tooth

Chemical Vapor Degreases Metals

AN apparatus for degreasing metal and other products prior to plating, enameling, or other finishing operations, has just been perfected as a result of the application of an ingenious chemical principle. In this process the material to be degreased is suspended in a bath of the vapor from one of a class of chlorinated solvents known under the trade name of Cecolene. The vapor, being much heavier than air, has no tendency to overflow but fills the container in which the parts to be cleaned are placed and condenses in contact with water-cooled condensers around the sides of the container and in contact with the cold objects being cleaned. It is claimed that the condensate carries all dirt and grease to the bottom of the tank where it remains in the liquid without danger of vaporization. The device is adaptable to gas, steam, or electric heating.—*A. E. B.*

British Fog Flying Experiments

SINCE England "enjoys" more fogs than any other country, the subject of fog flying is of real interest to the British Air Ministry. Its scientific staff has recently made some interesting and successful experiments in this direction, at the experimental station at Farnborough. The tests were made on a day of real fog, which extended 90 feet above the ground.

The apparatus used was simple in character. A small captive balloon was anchored 400 feet above the ground and about half a mile from the landing field. An airplane, an Avro biplane of standard make, carried a pitch, or fore-and-aft level, indicator and a turn indicator. A weight was suspended by a wire a few feet below the landing gear. The pilot left the landing field and flew above the fog, sighted the balloon and returned to the field at the appropriate gliding angle, by using his pitch indicator. When the suspended weight touched the ground, a red lamp gave him the signal for leveling out. Once the airplane left the ground it was not seen from the field until it had again landed. The experiment was repeated successfully five times and certainly adds to our knowledge of fog-flying technique.—*A. K.*

New Industries from Natural Gas

THE most remarkable development of industrial chemistry within the past decade has been the large-scale production of scores of entirely new chemicals from natural gas. Chemists have learned that they can juggle the constituents of natural gas around in a great variety of ways. The decomposition of natural gas (largely methane, ethane, and propane) at high temperatures is known as pyrolysis.

When methane is subjected to temperatures of 1800 to 2200 degrees, Fahrenheit, it breaks up, or "cracks." At slightly lower temperatures the parts reunite, but form new products as they combine. The higher hydrocarbon gases also break up and reunite to give various products different from the parent substances. At sufficiently high temperatures the gases will decompose to carbon and hydrogen.

In either type of cracking, hydrogen is always set free and by suitable means can be isolated and used commercially. Its major uses are as a reducing agent in the process industries; the hydrogenation of mineral and vegetable oils and coal; the synthetic production of ammonia and fertilizers; and as a refrigerant.

Other gasses formed in the pyrolysis of natural gas are acetylene, butadiene, ethylene, propylene, and butylene. Acetylene is used in welding and cutting metal, and may be used to prepare acetaldehyde, which is further used in silvering mirrors or in the preparation of medicinals such as chloral, a soporific. Butadiene, under proper treatment, condenses to form an artificial rubber having the same general composition as natural rubber. Ethylene has recently come into use in ripening fruits. It is also finding use as an anesthetic. However, its major use at present is the synthesis of ethylene glycol, an antifreeze for water-cooled motors, and the basis for a series of important lacquer solvents. If desired, ethylene may be converted to ethyl alcohol, widely used as a solvent, and also in the preparation of other compounds such as ether. Again, by proper reaction with chlorine, ethylene chloride is formed. This is a valuable solvent, especially for fats and essential oils, and is also used as an anesthetic. Propylene finds use as an anesthetic, and also in the synthesis of iso-propyl alcohol, which is being substituted for ethyl alcohol with good results in certain instances. Butylene is also used in the preparation of certain butyl alcohols which are finding use as solvents in the chemical industries.

The principal liquids formed in the pyrolysis of hydrocarbon gases are benzene, toluene, and xylene. Benzene is a very valuable product and forms the basis of many chemical processes. Thus are obtained aniline and the entire series of aniline dyes, and many explosives, perfumes, and medicinals. In addition benzene is an excellent solvent and anti-knock motor fuel. Toluene is the basis of the familiar T. N. T. (trinitrotoluol), of dyes, and of saccharin, a sugar substitute 400 times as sweet as sugar. Xylene is similarly used in the synthesis of dyes and other products, and also to a large extent as a solvent.

The solids resulting from pyrolysis are chiefly naphthalene and anthracene. Naphthalene is well known as an insecticide in the form of moth balls. It is also the basis for the important indigo dyes. Anthracene is used in the synthesis of alizarin dyestuffs. Finally, under certain conditions of cracking, there is obtained carbon black, widely used in making ink, in compounding rubber, and as a pigment for paint.—*A. E. B.*

Electrocution

WHEN a human being is subjected for a brief period to a considerable amount of voltage of either continuous or alternating electric circuits, changes are produced in the cells of his body. An engineer, aged 60, depressed because of ill health, made contact with an alternating current at 2200 volts potential. The current passed from his left hand to his left foot, and he may have been in contact for 20 minutes. Physicians in Baltimore made an investigation of the conditions of the cells of his body six hours after death. They found that the cells of the brain were swollen and had been badly injured by the current.

A man, 24 years of age, electrocuted for murder, was submitted to a voltage of 2200 for two minutes. When his brain was examined after death the same type of changes were found.

Rats were then electrocuted and real injuries were found in the nerve cells of the brain and spinal cord. Some of the greatest changes took place in the nerve centers in that portion of the brain which controls the breathing. If the shock is slight, the interference with the breathing is temporary and it is possible by the use of artificial respiration to bring about recovery. If the shock is continued for a long period of time the changes that occur are so definite and prompt that recovery is not possible.—*M. F.*

Artificial Silk from Peanut Shells

RAYON from peanut shells is under investigation by the Farm Wastes Division of the Department of Agriculture at Arlington Farms, Virginia, with results which seem to promise a large raw-material supply for viscose producers. Over 70,000 tons of peanut hulls are collected annually in southern shelling plants, but little use is made of them except as fuel for plant power. The fact that the hulls are collected is a point in their favor, since many other types of waste which might be used could not be made available in bulk without heavy collection costs. Research

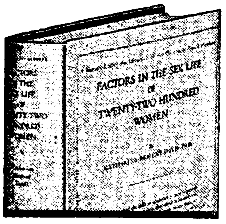
FACTORS IN THE SEX LIFE OF 2200 WOMEN

By KATHARINE BEMENT DAVIS, Ph. D.



This pioneer volume offers concrete factual data on the events in the sex life of normal women, supplying needed information on a topic which has long been the subject for uninformed conjecture.

Under the expert direction of Dr. Davis, two groups of selected women—married and unmarried—replied anonymously to questionnaires designed to elicit information on every phase of woman's sexual life. Full data on the various periods of life, as well as on so-called "abnormal" experiences were received.

This information was first tabulated. Then comparative statistical studies were made on the most important topics. The book offers specific data on many questions like: What factors seem to enter into the "happy" and "unhappy" married life? What are the causes and extent of abnormal practices? What is the importance of sexual education, etc.?

The clear and simple treatment makes the book invaluable to social workers, physicians, parents, educators; first, in developing a saner attitude toward the whole subject; second as a tested method in throwing light on sexual maladjustments as affecting personal relations.

The SCIENTIFIC AMERICAN says: "Almost to a certainty this book will upset a number of fondly cherished beliefs. It is a thoroughly scientific record of scientific work in sociology, performed by a noted scientific authority. The discoveries recorded were based on actual data secretly obtained." For free examination, use the coupon now. Price $3.50.

shows that a product up to 90 percent alpha cellulose content can be derived from peanut shells, the requirement of good rayon material thus being satisfied. Experimental fibers have been produced.—*A. E. B.*

Yeast for Cows Instead of Cod-Liver Oil

YEAST, which has been exposed to ultra-violet rays, is better than cod-liver oil for increasing the rickets-preventing properties of cows' milk, Dr. Harry Steenbock, Flora Hanning, and E. B. Hart of the Wisconsin Agricultural Experiment Station at Madison, Wisconsin, have found.

These investigators have been trying for some time to find a way of increasing the anti-rachitic property of cows' milk. The majority of infants fed on it get rickets. Earlier observations showed that summer-time milk had slightly more vitamin D, the rickets-preventive, than milk produced in winter. Experiments showed, however, that it was not because the cows were getting more ultra-violet light in summer that their milk had more vitamin D in it.

Next, experiments with the cows' diet were made. Cod-liver oil, which prevents rickets in man, was not satisfactory when fed to the cows. Fed in large amounts, it lowered the secretion of butter fat. Fed in small amounts, it produced little, if any, effect of an anti-rachitic nature.

Excellent results were, however, obtained from irradiated yeast. Two hundred grams fed daily to cows producing from 30 to 40 pounds of milk increased the vitamin D content of the milk many fold. Even 50 grams furnished enough vitamin D to make the milk highly anti-rachitic.

Apparently by the use of irradiated yeast one of the most outstanding deficiencies of cows' milk can be corrected in a practical way. With the present cost of yeast production, it should be possible to give milk all the vitamin D required for normal nutrition at a cost of a fraction of a cent per quart.

The use of yeast has a further advantage in that the amount of vitamin in the milk can be controlled by the feeding of a standardized yeast preparation in amounts adjusted to the milk production.

The applicability of the use of irradiated yeast for the enrichment of human milk still remains to be worked out.—*Science Service.*

Cleansing Chemical Is "Safe" Alkali

UNTIL recently sodium metasilicate (Na_2SiO_3) had not been available commercially because of the difficulty of preparing the crystals from the sticky mother liquors and the consequent inability to prepare a granular product which would not adhere or form a hard cake on standing. Chemists have now succeeded in overcoming these commercial barriers and sodium metasilicate is available as a dry soluble powder, which keeps indefinitely in a tight container at temperatures below 60 degrees, centigrade.

Sodium metasilicate yields strictly alkaline solutions which remain effectively alkaline until they are almost completely neutralized. The solution is efficient as a cleansing agent without the disadvantages met in certain other solutions of the same high alkalinity. The material seems well adapted to cleaning all sorts of material, including glass, metals, and alloys. It also has interesting applications in the laundry. —*A. E. B.*

Shelled Nuts Form Soap Deposit in Glass Jars

THE mystery of the frostlike deposit frequently seen on the inside of glass jars containing shelled pecans, or other nuts, has been solved by E. K. Nelson and H. H. Mottern, chemists of the United States Department of Agriculture. The deposit is soap, the chemists say, and it is formed by the action of the acid fat of the nuts on the alkali of the glass. It causes considerable financial loss in the sale of the product.

The unexplained presence of the soapy deposit has long been a source of annoyance to packers of shelled nuts and to some housewives in the south who put up shelled pecans in glass jars when the nuts are plentiful and inexpensive. Although the soap does not impair the quality of the nuts, it presents an unsightly appearance and reacts against the sale of the product.

The chemists first thought that the acid fat of the nuts had come in contact with minute amounts of alkaline cleaner left in the jars but this theory proved incorrect.

Further investigation showed that shelled nuts packed in ordinary glass containers formed the white deposit, whereas nuts put up in hard-glass containers at the same time and under the same conditions formed no deposit. It was concluded, therefore, that the soap was formed by the action of the nut fat on the glass.

Our Point of View

(*Continued from page* 253)

in their vigorous attacks on the treaty. But most Americans felt that, taking all matters into consideration, it was a good treaty. We think they reconciled themselves to this treaty in the firm belief that President Hoover would put the whole force of the administration behind a building program that would give the nation the maximum navy it is entitled to have under the treaty. In as much as the ratification of this treaty is a personal triumph for Mr. Hoover, the vigorous prosecution of the building program becomes a personal obligation of the President and his administration.

CONGRESS AND PARLIAMENT CONGRESS and Parliament adjourned almost simultaneously and neither had succeeded in accomplishing its major objectives. Despite the earnest efforts of the Congressionally-created Farm Board, the price of wheat and cotton is lower than last autumn, and the Labor Government in Great Britain, although unhampered by either the Conservatives or Liberals, has not only entirely failed to reduce the number of unemployed but has seen them increase by over 200,000. These two failures should warn the peoples of both countries that there is definite limitation to the powers of government to interfere with economic laws. There is truth in the homely old adage that God helps those who help themselves, and nothing so becomes a nation as the sturdy self-reliance of its industrial citizens.

BRITISH EMPIRE FREE TRADE AMONG the panaceas urged for its commercial depression is a tariff wall for the British Empire. To avoid offending the Free-Traders, this new proposal for an empire preferential tariff is euphoniously called "Empire Free Trade," but the essence of the system is a tariff against the rest of the world. The difficulties in creating such a system can be estimated by recalling the difficulties encountered by the Republican leaders in passing the last tariff bill through our Congress. All the struggles between the industrial and agricultural parts of the United States are foreshadowed on a larger scale between the industrial United Kingdom and her agricultural dominions. To obtain a preferential market for the products of her factories in her dominions, the United Kingdom must give them a compensating preferential market for their agricultural products. This means a food tax. And neither the Labor nor the Liberal party is prepared for such a departure from traditional British policy.

Even if the United Kingdom were willing to submit to a food tax it is doubtful if the Dominions would be willing to give British factory products much preference, for Canada, Australasia, and the Union of South Africa are all seeking to protect and expand their own infant industries. A Canadian leader expressed this idea very vigorously when he said in substance "A factory in Montreal strengthens the British Empire as much as a factory in Manchester."

In spite of the difficulties to be encountered in establishing reciprocity throughout the British Empire, many British readers, mostly among the Conservatives, are convinced that it offers the only solution for British unemployment. Much will be heard on the subject in the near future. As Canada and the United Kingdom are among our leading customers, our interest in the outcome is apparent.

OCEAN LINER COMPETITION WHILE the Naval Conference has placed definite limitations on naval competition, the struggle between the leading merchant navies of the world is proceeding at a faster pace than ever. It is noteworthy that in every case the governments of the competing countries are solidly supporting the private companies building and operating merchant vessels. Great Britain, Germany, and Japan have long subsidized their merchant marines; more recently France has also. Italy and the United States have come to the assistance of their commercial fleets. At present the British Cunard line, especially aided by the government, is planning a vessel that will be speedier than the German *Bremen*, and the French Government recently increased its aid to the French company that is engaged in building a liner, especially designed to add new luster to the French Line.

These wonderful liners, the western terminal of which is and will be New York, directly and indirectly add to the commercial prestige of a state and, in time of war, can readily be converted into auxiliary cruisers, or in some instances into aircraft carriers. Small wonder then that, in these days when governments realize they must help their own citizens in the competition for world markets, they willingly assist their own merchant marine. Somewhat tardily we have realized that we must give governmental aid to our merchant marine; a determined continuation of this policy will do much to regain our long-lost position of sea-traders.

As a result of our government's assistance, American private enterprise, naturally chary of competing with foreign lines, with their cheaper built and operated vessels, are consolidating and enlarging their maritime interests, and while they will encounter stiff foreign competition, we believe they can succeed as did their forbears during a similar competition in the first half of the last century. Already in the Pacific, American vessels are holding their own against foreign vessels; we confidently expect a like result in the Atlantic.

THE CHAOS IN CHINA RECENTLY the U.S.S. *Palos*, a small river gunboat doing patrol duty in the Yangste River, was fired upon by one of the numerous insurgent armies now laying waste their unhappy country. This incident may focus the attention of Americans for a moment on China, and it would be decidedly to their interests to give that wretched country a brief thought. China takes a large part of our silver, some wheat, and some cotton goods. With Chinese trade demoralized, naturally the demand for these articles disappears. And by so much we suffer. When to the Chinese situation is added the unsettlement of India, the other large silver market, the present low price of silver is understandable. Most of the world's silver is produced in Canada, the United States, and Mexico, and when the price of silver falls, our own silver producers and those of our two nearest neighbors and excellent customers suffer, so commercially we lose three ways.

No one can offer an off-hand solution to the problem of China, but it is plainly obvious that there will be no miraculous remedy. If the Great Powers continue to stand aloof and let the Chinese brigands calling themselves Generals continue their indiscriminate fighting and unholy looting of their own country, poor China may stew in her own juice but the supineness of the Great Powers will be somewhat punished by their reduced Chinese trade.

In these post-war days it is the fashion to condemn everything connected with pre-war diplomacy, but the old European Concert of Powers would not have tolerated the conditions that have existed for almost a decade in China. Our responsibility in China should no longer be ignored; by our insistence on the Open Door policy, quite proper in itself, we have effectually discouraged any independent European or Japanese intervention in Chinese affairs. We should, therefore, take the lead in offering some form of outside help to this distracted country which so plainly can not extricate itself by its own efforts. Our previous record of refusing to seize Chinese territory or even to accept concessions, has given the Chinese people confidence in our good will, so that they will be more inclined to accept advice and help under our sponsorship. Certainly we should not continue to watch with folded hands the ghastly struggles of our tormented neighbor across the Pacific.

Candidates for the
MEDICINE BALL DEGREE

Now is the time to start a course in Medicine Ball. No, it isn't like drinking catnip. It's a genuine sport, and, if you haven't played it, you are entirely out of style—healthfully and politically speaking. For aside from being a sport much approved by President Hoover, it is one of the most muscle-building, circulation-toning, fat-removing, blues-killing, back-yard or front-walk games ever invented for sedentary man. Read all about it in the October issue of HYGEIA, the Health Magazine of the American Medical Association. Minnie Martin, who has been a Medicine Ball addict for twelve years, gives in her vivid, humorous style, a set of suggestions for making Medicine Ball a wholesome zestful recreation for exercise-starved men and women. Working for your M. B. Degree is real fun.

WHOM
shall you consult

Many people who have trouble with their eyes trot off to the jeweler, who is also an optometrist, and have a pair of glasses fitted. They never dream that the trouble with their eyes might arise from complications in other parts of the body, or that the eye, itself, might require medical attention. *Optician, Optometrist, Oculist, Ophthalmologist,* or *Ophthalmic Physician,* which one is the man you need? You know that each one has something to do with the treatment of the eyes, but——. Dr. McCoy defines these titles for you in the October HYGEIA, helping to direct you to the right person for you eye troubles.

Other Health Topics
of vital interest to you

"Warm Water Healing" tells of a new treatment for paralyzed limbs; "The Antiquated Coroner System" explains a blunder in the legal processes of certain cities that is injurious to health and personal welfare; "Simple Lessons in Human Anatomy" is a "get-acquainted-with-your-body" series of articles that will help in health preservation; "Questions and Answers" is a monthly section of HYGEIA that clears up the health problems of its readers—these are only a few of the health problems treated in HYGEIA. Every topic is written by an authority who talks to you through HYGEIA as he would talk to a friend—in a personal heart-to-heart style that makes the reader want more and more of HYGEIA. Books Selected by the Editors

An Introduction to the Study of Wave Mechanics—*By Louis de Broglie*

A COMPLETE account of the new wave mechanics, including the Heisenberg theory, written by the original theorist de Broglie (see Scientific American, March 1930, p. 183) who suggested the wave atom. This 246-page book, translated from the French, contains an unusually well rounded discussion of the subject, is not popular, but involves college mathematics throughout. $4.50 postpaid. —*A. G. I.*

The Fundamental Theory of Electrical Engineering —*By A. L. Albert, Asst. Prof. E. E., Oregon State College*

BECAUSE of the recent developments in vacuum tubes, photoelectric cells, et cetera, a text of this kind was needed to cover completely present practice in fundamental electric phenomena. This presentation is equivalent to college or university courses and will be of value as a reference for non-electrical students. $3.40 postpaid.

Fundamentals of Architectural Design—*By W. W. Turner*

HERE is a dependable text and a ready reference for architects. It presents a concise treatment of all the fundamental principles of architectural design. The plates give both the module and part system of measurement. Dealing with five major fields of architectural design, each of which ordinarily commands a volume for itself, this text really comprises five books in one. The vital elements of each of these fields are presented along with well-rendered drawings and a full glossary of architectural terms. $6.20 postpaid.

English for Engineers—*By C. A. Naether and G. F. Richardson*

THERE is without a doubt a strong trend in engineering and industrial circles to set higher standards in the use of characteristic English. The various colleges and universities, particularly in the large centers of population, are offering courses specially prepared for the adult student. Prominent engineers are using every effort and opportunity to advocate some sort of standardization. This work is ably conceived and most carefully executed. It is a broad course readily adapted to manufacturing business generally and postulates that accuracy in any line should extend to expression as much as it is essential to the subject matter. $3.20 postpaid.

Ingenious Mechanisms—*By F. D. Jones, Editor*

ONE hundred and ten designers have contributed to this collection of the most ingenius mechanisms which are commercially practical. Designers and inventors will find the classification and description of this important work of 536 pages of invaluable aid in their work. As a reference it should be kept in every technical library. We quickly placed it on our shelves. For 15 years these devices have been collected, many of them having received prizes in competition. A needed and welcome work amply illustrated. $5.25 postpaid.

> INFALLIBILITY is not one of the characteristics of an editor, although many of our readers apparently compliment us with this attribute. No one person, in fact, no single editorial staff, can answer every one of the diversified group of questions that come in our mail. Usually we can give some authoritative reference; sometimes on minor, unimportant queries, we must simply say we have no information, but here is one which should have an answer: "What literature is available on the dynamics of small boat sailing?" Our own references failed us. We wrote to our good friend, the Editor of *Yachting* and he replied that the older texts we ourselves located were somewhat antiquated; that a revised edition of one of the standard works would appear shortly, but at present there was nothing but the older issues.
>
> Have patience, therefore, if we cannot always serve you, but do not hesitate to send your book queries to L. S. Treadwell who edits these pages.

How To Become A Radio Amateur

A VERY complete little booklet of 30 pages describing in detail how anyone interested in radio can take an active part in the fascinating pastime of amateur radio communication. First, something is told of the ease of constructing amateur radio equipment. Then follows a short dissertation on learning the code. A very simple yet complete vacuum tube receiver and a low powered transmitter, both for use on the "80-meter" band, are described in minute detail so that the reader can at once start construction. The latter part of the booklet is devoted to telling how the interested person can pass the necessary examination for obtaining a first grade amateur's license. For this booklet write direct to the publishers, American Radio Relay League, Hartford, Conn.—10 cents—*A. P. P.*

Science in Soviet Russia—*By J. G. Crowther*

THE author of the unusually interesting article "Super Magnetic Fields," in the June Scientific American, himself a scientific man, recently visited each of Soviet Russia's scientific research institutions, testing and other laboratories and institutes, and has given his readers a clear, graspable picture showing just what actually is going on—and there really is quite a little—in science pure and applied in that strange civilization. $3.00 postpaid—*A. G. I.*

The Skeletal Remains of Early Man—*By Dr. Ales Hrdlicka, U. S. National Museum*

A NEW and noteworthy scientific treatise containing lengthy detailed descriptions of all the famous finds of ancient man: Foxhall, *Pithecanthropus*, Piltdown man, Heidelberg man, Rhodesian man, all the Neandertal skeletons, and others, by a famous authority. Suitable for the general reader. Because of its origin with the Smithsonian Institution, the volume is priced about at cost, $2.25 (unbound), otherwise it would be at least a five-dollar book. It is suggested that purchasers order it direct from the Smithsonian Institution, Washington, D. C.—*A. G. I.*

Sound Pictures—*By J. R. Cameron and J. F. Rider*

"THE purpose of this book is to acquaint those coming in contact with sound equipment with sufficient fundamentals pertaining to sound motion picture equipment involved at the recording and reproducing end, to enable them to assume freely the responsibilities of operation and maintainance"—so runs the foreword. It contains 1074 pages, abundantly illustrated, starting with the structure of matter and proceeding through the whole field to the very latest adjuncts and accessories. There was real need for such a work and one will quickly realize that it has been amply met here. Both authors are experts and authorities and yet the treatment is so clear and comprehen-

From Recent Publications

sive one can readily assimilate the technicalities by a little application. A most creditable accomplishment. $7.70 postpaid.

THE CONDENSED CHEMICAL DICTIONARY—*Thomas C. Gregory, Editor*

A SPLENDID reference for people not educated along chemical lines but who seek information regarding chemicals and other substance used in manufacturing and laboratory work. This second edition is completely revised, reset, and enlarged and gives a surprising amount of information in most condensed form. Many useful tables comprise the appendix. $10.20 postpaid.

READINGS IN PSYCHOLOGY—*By R. H. Wheeler, Univ. of Kan.*

CAREFULLY selected passages written for the purpose of giving student beginners access to experimental investigation, selected first by what seems to be the dominant interest in psychology, and second by accessibility for publication. This is a sort of laboratory manual, with editorial notes, glossary, and index. There are seven groups in all, with a total of 28 readings. 568 pages of text. $3.95 postpaid.

WHEN I WAS A GIRL—*By Helen Ferris*

WELL told short biographies of Schumann-Heink, Janet Scudder, Marie Curie, Jane Addams, and Etsu Sugimoto, all of whom achieved success in spite of almost insurmountable obstacles, in the fields of music, art and social service, or science. Inspirational and most readable. $2.65 postpaid.

EVOLUTION OF THE FLYING MACHINE, BALLOON, AIRSHIP, AND AEROPLANE—*By Harry Harper*

WITH the background of 25 years of flying, giving as it did unusual facilities for acquiring material of special interest, the author has assembled more incidents of early flight than we have yet seen under one cover. English and Continental flying is particularly well covered and a most complete chronology, especially of early attempts at flight, casualties, et cetera; completes a thorough work. $5.20 postpaid.

TWENTY THOUSAND MILES IN A FLYING BOAT—*By Sir Allan Cobham*

THE very entertaining and sometimes thrilling experiences of this celebrated pilot during his circuit of Africa in a large seaplane. As a messenger of goodwill, he did much to open up many hitherto inaccessible places. $2.65 postpaid.

MANUAL OF FLIGHT—*By Ienar E. Elm, Capt. U. S. A. (Ret.)*

KNOWN as the author of several successful technical books, here he has recorded the fundamental knowledge that should be part of the equipment of every man or woman who intends to fly. Elementary and advanced maneuvers are covered in detail and the actual hazards and safety of air travel are judiciously set forth. Emergencies are considered together with the best means of escape. An intimate and accurate outline of the art is given in most workmanlike fashion. A very practical and conclusive manual. $3.20 postpaid.

PRACTICAL NAVIGATION—*By Charles H. Cugle*

"THERE are many excellent books on the theory of navigation, but very few that the ordinary man can understand and this book has been published with theory eliminated entirely,"—so runs the preface. Practically everything that is needed at sea is included in this most excellent text of 574 pages—innumerable examples of calculations as well as rules, deck information, examinations, stowage of cargo, et cetera. No short cuts are given, for the author believes these should be used only after thorough familiarity with the old tried and true methods. A most thorough and practical manual. $7.20 postpaid.

EXIT—*By Harold Bell Wright*

FOR three years no novel has issued from this author, the legends of the Papagos Indians being the intermediate title. Somehow one feels that in this present novel some of the mysticism, the intangible, the searching after inchoate realities, aspects which give fascination to Indian lore, has influenced the approach to "Exit." There seems to be less of the joyous forward looking into life which has been so characteristic of this writer; we seem to find more of introspection, spirituality, and the influences of past persons and events. Genuinely interesting from this viewpoint and as fascinating in style and description as ever. $2.00 postpaid.

BLACK SOIL—*By Josephine Donovan*

A STORY of community life on the prairie of northwestern Iowa, consisting of several nationalities which eventually become banded by their vicissitudes and common hardships. The author is well known for her literary work along historical lines and this, her first novel, received the 2000 dollar prize offered by the publisher. Needless to say the story runs with intriguing smoothness and fluency. $2.65 postpaid.

CONTEMPORARY IMMORTALS—*By Archibald Henderson*

WITH the keen insight of an artist and scientist, the author analyzes the lives, both purpose and accomplishment, of 12 of the most productive characters in modern affairs. Swiftly and clearly he delves to the bottom and reveals for us the salient facts which form the fundamental foundation of their impulses, their character, their accomplishment. The analytical mind of the mathematician supplemented by the culture, the language, and manners of many nations has produced one of the most delightful books we have had the pleasure of reading in many a month. Einstein, Gandhi, Edison, Mussolini, Shaw, Marconi, Addams, Wright, Paderewski, Curie, Ford, and Kipling are the sketches given. $2.65 postpaid.

Facts and Notes of Interest to Inventors, Patentees, and Owners of Trademark Rights

Adding Machine Inventor Dies

THE ranks of American inventors lost a valuable member when Dorr Eugene Felt passed away recently at his home in Chicago. Born in 1862, his mechanical bent first made itself evident at the age of 14 when he went to work in a machine shop. Early in the 80's Mr. Felt conceived the idea of the adding machine. From an old box, some metal meat skewers and a few rubber bands and staples, he evolved his first model of the machine that was destined to make an important niche for itself in the business world. From this early start Mr. Felt invented and patented numerous mechanical devices. He also found time to interest himself in other phases of science. He was an ardent student of geology and of Biblical history, both of which trends developed during his wide travels in foreign lands.

Central Radio Patent Bureau

WHAT appears to be an important step toward the solution of patent troubles in the radio industry has been taken by the Radio Manufacturers' Association. Establishment of a central patent bureau to collect and disseminate complete information on radio patents was ordered recently by the RMA Board of Directors. The new patent department will be in the New York offices in charge of a competent radio patent attorney.

An extensive library on radio patents, foreign as well as domestic, will be developed in the new patent department. It will collect, digest, and index all radio patents and publications and all information regarding patent litigation. Files of many important manufacturers who are members of the RMA will be centralized in the patent department, which will advise manufacturing members of radio suits and decisions, applications for and issuance of radio patents.

The new patent department will not participate in any patent litigation, but its patent data will be available to all members of the association.

"Gas Saver" Ad Censored

ADVERTISING in connection with the sale of a "vaporizer and decarbonizer" for automobiles that light cars run 57 miles on a gallon of gasoline, is prohibited in an order of the Federal Trade Commission to J. A. Stransky and L. G. Stransky, copartners trading under the name of J. A. Stransky Manufacturing Company at Pukwana, South Dakota.

Among other phrases contained in the company's magazine advertising was the following:

"Five hundred dollars per month selling a new patented fuel vaporizer guaranteed to save up to 50 percent in gasoline: 40 miles per gallon made with Ford car."

Representations made by the company were found to be exaggerated beyond what was possible of accomplishment as a result of the use of the "vaporizer and decarbonizer" device, and statements to the effect that the device would remove carbon, prevent spark trouble and over-heating, and make engines start easier, were found not to be substantiated in fact.

The order of the commission prohibits, among other, such representations as the following:

"Ford runs 57 miles on gallon of gasoline."

"Ford makes 40 to 57 miles to gallon; other cars show equally remarkable gains; increases power 25 to 50 percent."

"Why not buy gasoline for 10 cents per gallon? New invention. Cuts fuel bills 25 to 50 percent.

"An automobile goes 27 miles on air by using an automatic device which was installed in less than five minutes. The automobile was only making 30 miles on a gallon of gasoline, but after this remarkable invention was installed, it made better than 57."

"Makes more miles per gallon than any other device on the market, regardless of the price."

"This wonderful little device cuts the cost of gasoline in half—it made it possible for an auto to go 60 miles on a gallon of gasoline."

"Enables Ford cars to make as high as 61 miles to the gallon of gasoline."

Aircraft Patents Issued

A MISCELLANY of devices, including one design for a super-airplane combining the principles of both lighter and heavier than air craft, is included among the patents issued recently to aeronautical inventors by the United States Patent Office. The "super"-flying craft, the invention of Hugh J. Ross of Cliffwood, New Jersey, comprises a fuselage, gas bags surmounted thereon, motor driven propellers on the sides of the fuselage and means for rockably mounting the propellers on vertical axes for control from within.

Another giant airplane, but not containing the gas bag support, was patented by Bert Messick of Lansing, Mich., and an airplane with wings having air-compressing plates depending from their under surfaces at right angles was patented by George S. St. Louis of Fresno, Cal.

The late Elmer A. Sperry obtained a patent on a beacon system for night flying. Another safety device, a parachute supported by a standard, designed to bring a plane safely to earth, was patented by Frank Arnaiz of Los Angeles. An electrical heating means for airplane wings to prevent the accumulation of ice and snow is the invention of William S. Ingram of Philadelphia.

Patents covering a "means of controlling the angle of incidence of aero revolving blades or wings and propellers" were issued to David Kay of Blackford, Scotland. Martyn Clissford MacPherson of Hayes, England, obtained a patent on a "braking of the under-carriage or landing wheels of airplanes." Hugo Junkers patented a dock for flying machines, and a patent on a floating dock for seaplanes was issued to Paul Degan of Kiel-Dietrichsdorf, Germany. Another German, Otto Krell of Berlin, patented a rotable movable hangar for dirigibles.

Increasing interest in the development of lighter-than-air craft is evidenced by the number of patents pertaining to dirigibles recently issued.

Wolfgang B. Klemperer, for example, procured three patents covering a stabilizing apparatus for airships, a tensiometer, and a bulkhead for airships, collaborating on the last with Paul Helma, also of Akron, Ohio. Their patents and one issued on a gas container for airships to Karl Huerttle, together with another on a wire netting for airships to Paul Helma and Kurt Bauch, all of Akron, have been assigned to the Goodyear-Zeppelin Corporation. These technicians are among those working on the construction of two giant dirigibles for the United States Navy.

Ralph H. Upson, famous balloonist of Brooklyn, New York, procured patents on a dirigible and a type of airship fin which he has assigned to the Aircraft Development Corporation of Detroit. Charles Guidice, also of Brooklyn, designed and patented a new type of dirigible, and a patent on a device for protecting balloons from lightning and other atmospheric disturbances was granted to Alfred Crossley, Washington inventor, who has assigned his rights to the Federal Telegraph Company.

Patents on new types of parachutes have been issued to Charles H. Castagne of Chicago and Captain Edward L. Hoffman of Dayton.

Lloyd Stearman of Wichita, obtained patents on a dolly for airplanes and an air-intake heater, both of which inventions he has assigned to his Stearman Aircraft Company.

Cologne Trademark Void

IN a recent decision by the United States Circuit Court of Appeals, Judges Manton and Swan concurring and Judge Hand dissenting, it was ruled that Muelhens and Kropff, Inc., 25 West Forty-fifth Street, American manufacturers of 4711 eau de cologne, cannot have exclusive right to the use of "4711" as a trademark because the concern does not possess the original formula for the manufacture of the article.

Since 1792 the Muelhens family in Germany has been manufacturing eau de cologne at 4,711 Glockengasse, Cologne, Germany. The formula has remained a secret.

In 1878 William Kropff came to this country as the family's agent. Later a member of the Muelhens family formed a partnership here with him. The trademark "4711" was registered as belonging to the firm, but the secret formula was never revealed to Kropff.

During the World War the Alien Property Custodian seized Muelhen's interest in the firm and later sold it to Kropff. The sale included good-will and the trademark. Kropff then incorporated as Muelhens & Kropff and made and sold a cologne under the trademark "4711."

After the war, Muelhens established Ferd. Muelhens, Inc., and began selling "4711" cologne made according to the old formula. The result was that Muelhens & Kropff brought suit to prevent Ferd. Muelhens, Inc., from using the trademark.

A majority of the court decided that "assignment" of the receipt is essential to give the assignee the exclusive right to a mark which denotes a product manufactured thereunder. Otherwise the public will be unable to procure the genuine product under the name by which it has always been known.

Those who insist upon the genuine 4711 eau de cologne are not the prospective customers of the plaintiff, for he cannot supply it.

"Special" Book Editions Curbed

A BOOK publishing partnership signed a stipulation with the Federal Trade Commission agreeing, in connection with the sale of a special edition of a book, to cease and desist from using such representations as "The Authentic Text," "The First Authentic Text," or "The Complete Text" as descriptive of the edition, when in truth such statements are not supported in fact.

This firm also agreed to discontinue use of the words "authentic" and "complete" in any way that would imply or deceive the purchasing public into believing that its edition is an authentic one of Edgar Allen Poe's story entitled "The Gold Bug," or that the edition is an authentic or complete text of this story containing all of Poe's alterations and additions, when such is not the fact.

Patent Office Rules Revised

AMENDMENTS to the trademark rules and to the rules of practice of the Patent Office, made to conform to the new law (act of Apr. 11, 1930), relating to fees, and certain recommendations of the committee of the American Bar Association were announced recently by the Commissioner of Patents, Thomas E. Robertson.

"That part of the new rules which includes fees," Mr. Robertson stated, "has been changed to meet with the requirements of the new law approved Apr. 11 providing that the fee for issuing original patents shall be 25 dollars and 1 dollar for each claim in excess of 20, instead of the present fee of 20 dollars and 1 dollar for each claim in excess of 20.

"Amendments to the rules of practice of the Patent Office were made to carry out the recommendations of the patent committee of the American Bar Association. These changes are, first, an amendment to Rule 41, which provides that more than one species of invention, not to exceed three, may be claimed in one application if that application also includes an allowable claim generic to all the claimed species.

"The changes in rules 109, 114, 122, 123, 124, 128, and 130 provides that all motions in interference cases shall be heard by an examiner of interferences instead of by a law examiner as at the present time.

The American Bar Association, it was pointed out, believes that this will expedite work in interferences, lessen the trouble and expense of interferences and bring them to a speedier conclusion.

In the first sentence of rule 109, "An applicant involved in an interference may, at any time within 30 days after the preliminary statements (referred to in rule 110) of the parties have been received and approved, on motion duly made, as provided by rule 153, file an amendment to his application containing any claims which in his opinion should be made the basis of interference between himself and any of the other parties," has been taken out of the rule and supplanted by the following:

"An applicant involved in an interference may, within a time fixed by the examiner of interferences, not less than 30 days after the preliminary statements (referred to in rule 110) of the parties have been received and approved, or if a motion to dissolve the interference has been brought by another party within 30 days from the filing thereof, on motion duly made as provided by rule 153, file an amendment to his application containing any claims which in his opinion should be made the basis of interference between himself and any of the other parties."

The rules from 109 to 130 provide for the substitution of the word, "examiner of interference" for "law examiner."

Rules 162 and 163 contain changes relating to the filing of typewritten instead

Advertisements in this section listed under proper classifications, rate 25c per word each insertion; minimum number of words per insertion 24, maximum 60. Payment must accompany each insertion.

Anyone desiring official copies of patents herein listed may secure them by remitting 15 cents for each one (state patent number to insure receipt of desired copy) to Munn & Co., 24 West 40th Street, New York City.

Pertaining to Aeronautics

AEROPLANE—Having a single wing extending longitudinally of the fuselage at a sufficient height and angle to dispose the load forwardly and so balance it, as to cause the plane to come out of a fall and glide safely to earth. Patent 1769320. Henry C. Thompson.

AIRCRAFT—Having an arrangement of supporting and flying control surfaces, by which the usual form of tail assembly can be dispensed with, and yet the craft maneuvered and maintained on a desired course and under perfect control. Patent 1766390. Charles V. Lapin.

AEROPLANE—Of the amphibian type, equipped with a landing gear, well adapted for water or ground, having novel features of material advantage in taking off from water, and means for preventing sleet and snow collecting upon the wings. Patent 1769393. John T. Rydberg.

Pertaining to Apparel

GARMENT—So constructed that when worn by a patient undergoing treatment for certain diseases, parts of the garment may be adjusted so that only that part of the body effected, need be exposed to view. Patent 1766272. Samuel W. Vallier.

Chemical Processes

PROCESS OF STABILIZING CEREAL BEVERAGES—Containing less than 0.5% of alcohol, by treating the beverage, at any stage of the brewing, with tannin and a siliceous clay, to precipitate the undesirable albuminoids which render the finished beverage turbid when chilled. Patent 1766428. Donato Cozzolino.

Designs

DESIGN FOR A DRESS—Patent 81493. Dorothy Long.

DESIGN FOR A COAT—Patent 81494. Dorothy Long.

DESIGN FOR AN ENSEMBLE SUIT—The inventor has been granted two patents, 81495 and 81496. Dorothy Long.

DESIGN FOR A RADIATOR-CAP ORNAMENT OR SIMILAR ARTICLE—Patent 81530. Guy de Vall.

DESIGN FOR A COAT—Patent 81545. Dorothy Long.

DESIGN FOR A READING CABINET—Patent 81568. Charles J. Abeles.

DESIGN FOR AN ENSEMBLE SUIT— The inventor has been granted two patents, numbers 81589 and 81590. Dorothy Long.

DESIGN FOR LACE—Patent 81616. Ben. A. Ball.

DESIGN FOR A DOLL OR SIMILAR ARTICLE—Patent 81638. Adolph Gramlich.

DESIGN FOR A TOY ANIMAL—Patent 81646. John S. Hooks.

DESIGN FOR A DRESS—Patent 81711. Dorothy Long.

DESIGN FOR A CARPET SWEEPER—Patent 81669. Earle R. Smith.

Electrical Devices

CIRCUIT-CONTROLLING DEVICE—Whereby special mechanism actuated by the steering apparatus of an automobile keeps the circuit of the indicating lights closed so long as the front wheels of the car remain turned in either direction. Patent 1766993. Masao Hasegawa.

THERMOSTATIC ELECTRIC SWITCH—More particularly designed for controlling the illumination of one or more incandescent lamps such as are used in direction signals, in a manner to produce an automatic flashing. Patent 1766430. Clarence K. Davis and Arthur Dick.

RADIO RECEIVER—Having means whereby the volume of output may be easily and accurately controlled from a point remote from receiving set to give desired softness or loudness, adapted for use with any type of receiving apparatus. Patent 1769256. Allen S. Clarke.

of printed briefs and records providing the brief or record does not exceed 125 pages.

"The Bar Association Committee requested that this be done to cut down printing expenses since they are now very high," Mr. Robertson said.

Bottle Trademark Denied

IN a recent decision, First Assistant Commissioner Kinnan held that the Obear-Nester Glass Company of East St. Louis, Illinois, is not entitled to register, under the Act of 1920, the words "Individually Wrapped," as a trademark for prescription bottles made of glass.

The ground of the decision is that the words could not function as a trademark.

In his decision, the First Assistant Commissioner said:

"The words sought to be registered as a trademark would have no trademark significance to the purchaser of the goods nor could they have any such significance as they merely convey the plain information as to the manner in which the bottles are packed or arranged for shipment. No one could obtain the exclusive right to use these purely informative and descriptive words in connection with the sale of bottles."

"Bucyrus-Erie" Registrable

AN applicant already owning registrations for the mark "Bucyrus," under the 10-year proviso of the act of 1905, is entitled to registration as a trademark of the word "Bucyrus-Erie" for power shovels and similar articles, the Assistant Commissioner of Patents has held.

While the word "Erie" taken alone is a geographical name and therefore would not be registrable, the opinion states that the combination of the two words, linked together, are to be considered as an entirety, and therefore, the mark does not fall within the provision prohibiting the registration of merely a geographical name or term.

Mis-branded Wood

TWO corporations selling and distributing motor boats have signed stipulations with the Federal Trade Commission agreeing to stop misrepresenting their products as made of mahogany, when such is not the fact. Both companies agreed to cease use of the word "Mahogany" either independently or in connection with the word "Philippine," or in any way which may tend to deceive the public into believing that their motor boats are made in whole or in part of wood derived from trees of the mahogany family, when such is not the fact.

One of the companies also will discontinue use of statements or representations implying that it owns, operates, or controls a factory wherein are built and manufactured the products it sells.

Labels Need Not Be Detailed

THE portion of an order of the Federal Trade Commission requiring a person doing business under the firm names to state the ingredients and percentages of such ingredients which make up a substitute shellac in labels and advertisements of the product has been held by the Circuit Court of Appeals for the Second Circuit to be unwarranted.

The court stated that it would be sufficient to prevent a fraud upon the public if the respondent labels his goods and advertises the same as "shellac substitute" or "imitation shellac," accompanied by the statement that it is not 100 percent shellac, and that it was not necessary to show the ingredients of the product in their percentages.

The Federal Trade Commission had issued an order against the respondent requiring him to cease and desist from using the word "shellac" in labels and advertisements of varnish which was not composed entirely of shellac gum dissolved in alcohol. The order permitted the use of labels and advertisements in the sale of the product if accompanied by words clearly indicating the other ingredients and the percentages used. The appellate court modified the order, by eliminating the latter requirement.

LINE TESTER—For overhead wires, wherein the structural arrangement is of such character that effective contact with the circuits to be tested, will be made regardless of the amount of corrosion, rust, etc., with which the surface may be coated. Patent 1769248. Charles D. Williams.

Of General Interest

WINDOW BOX—Or window refrigerator, which may be easily adjusted to the sill, does not interfere with the opening or closing of the window, provides fresh air while excluding dust, and prevents cold air entering the room. Patent 1769740. John C. Kelley.

CLOSURE CONSTRUCTION — For rubber pouches, hot water bags, and the like, which will be water-tight, less bulky than those in general use, and may serve with a tube so that the article may be used as a syringe. Patent 1769259. Beulah L. Henry.

EMERGENCY SECTION FOR SHIPS—Which will float free if the ship should sink, accommodate all of the people carried by the ship and enough storage of food and equipment to take care of them until rescued. Patent 1768152. Charles F. Rodin.

CIGARETTE CASE AND LIGHTER—In combination, constructed to take up very little more room than that occupied by a standard cigarette case. The lighter is removable for permitting a new refill in the operating mechanism. Patent 1766320. Edward G. Ahrens.

BOAT-SALVAGING DEVICE—Built in as a part of the boat and accessible from the deck, thereby obviating the necessity of passing cables in the mud beneath the ship bottom, for applying hoisting tackle to the sunken vessel. Patent 1769353. Louis F. Long.

LAWN SPRINKLER—Embodying mechanism whereby when the device is placed at the approximate center of a square, the volume of water will be controlled so that the corners will be reached by the spray, and the lawn uniformly sprinkled. Patent 1766514. Henry L. Henry.

SIGN—Constructed for interchangeably holding readable indicia in fixed position on a board, and against accidental displacement, yet allowing when desired an adjustment or spacing of the characters without removal. Patent 1766362. James A. Sears.

ENVELOPE—Which does not require moistening in order to effectually seal it, and in which means is provided for showing at once any attempt to open the envelope. Patent 1768836. Thomas E. Gjorup.

BRUSH—A folding brush in which the bristles are adapted to be received when folded within a protecting housing, the whole forming a compact structure which when unfolded provides a handle and brush. Patent 1770344. Frederick E. Schmidt.

BOX OR CONTAINER—Formed of cardboard and composed of three main parts having flanges projecting from the sides and ends which are joined together by metal staples or other fastening means operating as a protective means against damage by dropping. Patent 1770819. Fred W. Tamke and George W. Boh.

VISIBLE CARD FILE—Having a transparent pocket at the end of each card holder, which will improve the use of the record slip for the permanent items relating to the record matter, and the general operation of the file. Patent 1770793. Luigi Lombardini.

WEED PULLER—Having a pair of pivotally mounted jaws with ground penetrating points adapted to be moved together in gripping relation for removing weeds including their roots, with a minimum displacement of the soil. Patent 1771353. Fred P. Riddell.

1929 French Aircraft Exports Increased

FRENCH aircraft exports during 1929 increased considerably, Automotive Trade Commissioner W. L. Finger, Paris, France, recently informed the Department of Commerce. Land planes with a total value of 209,581,000 francs (approximately 8,207,411 dollars) were exported as compared with 138,898,000 francs (approximately 5,446,190 dollars) in 1928; seaplanes exported amounted to 4,852,000 francs.

The largest markets for French aircraft were Yugoslavia, Belgium-Luxemburg, Turkey, Rumania, Brazil, and Indo-China. In 1929 Yugoslavia imported from France aircraft valued at 40,290,000 francs; Belgium-Luxemburg, 2,713,000 francs, and Turkey, 2,694,000 francs. Although 1929 was the first year that France imported airplanes, the quantity was small. These planes came from Great Britain and The Netherlands.

Fraudulent Implication Stopped

CO-PARTNERS engaged in the sale and distribution of knit goods, such as sweaters, swimming suits, and knit dresses, recently signed a stipulation with the Federal Trade Commission agreeing to stop use of the words "Knitting" and "Mills" in their trade name so as to imply that they own or control a factory in which they manufacture the goods they sell.

They agreed to discontinue any other use of the two words which may have the tendency to mislead the purchasing public into the belief that these partners operate a factory.

Mine Safety

THE possibility of eliminating the use of electrical equipment in coal mines in Utah and substituting compressed air apparatus, will probably be considered by the state industrial commission, according to O. F. McShane, a member, who is investigating coal mine explosions.

It is stated that recent explosions have been caused by ignition of gas by the use of electrical equipment and Mr. McShane is serving notice on coal producers that they must show within a reasonable time that they can control this danger by introduction of new safety devices.

Compact-Holding Ring for Vanity Cases—Wherein spaced fingers are used to resiliently hold the compact plate in position, the fingers being so arranged that an implement may be placed there between for ejecting the plate. Patent 1771337. William G. Kendall.

Adjustable Handle—Whereby brushes, mops and such articles may be releasably held in different angular positions to enable a person to more conveniently carry out cleaning operations. Patent 1771325. John R. Cotter.

Device for Producing and Dispensing Lather—Having means for agitating the soap and water to produce a lather without the necessity of shaking the device, and to insure the dispensing of the lather only, precluding the discharge of water. Patent 1771292. Frank P. Gallipoli.

Ironing Board Attachment—By which those parts of garments which have been pressed, and depend from the board as a result of shifting to press other portions, are effectively supported to prevent contact with the floor and soiling. Patent 1770890. Frank Pons and Levert W. Wilson.

Hardware and Tools

Pipe Coupling and Rotary Tool Joint—In which a plurality of threaded sections are screwed into each other with the threaded sections having a differential pitch, and means for locking certain of the sections against independent rotation. Patent 1769381. Gustavus A. Montgomery.

Safety Spring—Or door closing device, having means for limiting the outward movement of a door or other hinged member, in order to protect the hinges, or any object with which the door might collide. Patent 1771299. Fred E. Justus.

Machines and Mechanical Devices

Washing Machine—Which may be connected by a hose to a house faucet and either hot or cold water used for the operation of the machine and for constantly passing clean water in contact with the clothes. Patent 1769221. Harley A. W. Howcott.

Tension Indicator and Compensator for Warping Carriages—For textile fabric such as rayon, silk, and fine counts of cotton, etc., particularly adapted for producing rayon becase it overcomes the action of jerks on the warp sections when starting and stopping, thus avoiding stretching. Patent 1769244. William G. Trautvetter.

Variable - Speed Transmission — Which makes use of two friction discs and two friction wheels, the construction permitting the gears to be bathed in lubricant while still keeping the discs away from the lubricant, thus operating efficiently at all times. Patent 1766240. Julius L. Allen.

Jig—For separating ore or minerals from rock or lighter material, and more particularly a jig wherein a pulsating column of water is used in conjunction with a grate to effect a classification of a bed of material. Patent 1769287. Asa R. Chase.

Moulding Machine—Wherein dough can be molded into mass of the same thickness throughout, such as pan bread, of a predetermined length, or shaped to provide rolls or loaves known commercially as French or Vienna bread. Patent 17711 (reissue). Frank A. Scruggs.

Wave and Tide Motor—Characterized by a plurality of floats capable of being mounted in a body of water for movement in response to wave action, and means responsibe to variations of levels, such as resulting from tidal action. Patent 1766457. Charles H. Ruth.

Automatic Alarm Clock for Hotels—By which the occupant of any particular bedroom may be rung up at any desired hour, an electric lamp being lighted at the same time in his sight, the alarm is automatically repeated a second time. Patent 1769830. Vlderico Giomi.

Apparatus for Treating Asphaltic Oils for the Production of Asphalt—Whereby asphaltic oils can be treated to produce oxidized asphalt possessing a relatively high melting point and a relatively low degree of penetration, and the time required for distillation greatly reduced. Patent 1766446. Max R. L. Miller.

Bun-Cutting Machine—In which a rotary cutter or knife is employed for cutting buns or other bakery or food products, without marring or making them objectional in appearance, the machine may be adjusted to completely sever or cut partly through. Patent 1766450. John A. Ost.

Sugar Dispenser—For mechanically delivering measured quantities or any multiples thereof, the several quantities being accummulated within the dispenser and all being discharged as a single quantity by one tilting movement, the parts are readily removable for cleaning. Patent 1768091. Gus N. Adair.

Loom Mechanism—A reed-like batten with mechanism for moving the same toward and from the fell, beating up the filling as it is inserted and coincidently effecting a combing of the work shed. Patent 1770269. Benjamin D. Hahn.

Lubricating Device—Including a well from which a capillary feeding element immersed in lubricant leads to the parts to be lubricated, and whereby a constant level is maintained in the well, whereby uniform feed is obtained. Patent 1770036. Albert Johnson.

Grinding Fixture—Capable of accurately grinding the face radius and sides of both large and small milling cutters and backing off to proper clearance in one operation, can be used on any standard machine. Patent 1770318. Andrew McAndrew.

Lock—Of the portable or "padlock" type, having a shackling element formed for general application and capable of assuming different angular positions without presenting an obstruction, but held locked against unauthorized removal. Patent 1770812. Ellsworth F. Seaman.

Vacuum and Pressure Pump—Which after reaching a constant speed will produce a definite pressure or vacuum, and once such pressure or vacuum is attained the pump will not operate to increase it beyond this maximum. Patent 1769257. Ralph G. Demaree.

Boat Davit—In which the use of blocks and tackle are eliminated, is vertically movable with the sides of the ship, maintains the boat at a fixed distance from the ship, and prevents upending of a boat during launching. Patent 1771372. Julian W. Bournier.

Dishwashing Apparatus—Having a plurality of brushes of different characters and configurations, connected for rotation with a motor shaft, whereby plates, platters, glasses and other tableware may be rapidly cleansed. Patent 1771934. Mattia Marangoni.

Washer—Having a steam jacket and heads securely bolted to the grooved rings on the ends of a cylinder, the inner face being entirely lined up with sheet nickel, particularly adapted for use in connection with the dry cleaning of clothes. Patent 1771638. Wallace C. Johnson.

Medical and Surgical Devices

Surgical Appliance—By means of which a constant temperature may be maintained with solutions such as "the Murphy drip" intravenous injections, saline and other solutions, as well as solutions for feeding the human body, and for blood transfusions. Patent 1770832. Donnie L. Bass.

Prime Movers and Their Accessories

Protecting Tray for Valve Chambers—Capable of being readily applied, and in such position as to form a protecting covering to receive and collect the carbon particles, cuttings and other waste matter, in such manner as to prevent contamination of the oil. Patent 1766469. Chauncey H. Stout.

Pertaining to Recreation

Toy—In the nature of a "hobby-horse" but differing by the employment of a structure that will produce a more bouncing motion, as well as a rocking motion, thereby exercising the abdominal, back and leg muscles. Patent 1771920. Benjamin Gordon.

Pertaining to Vehicles

Automobile Door Hinge—Whereby entrance to the front and rear seats is had by way of a single door, capable of being opened on both the front and rear edges, thus facilitating ease of entrance or exit from rear or front seat. Patent 1769273. Jacob A. Penner.

Tire-Deflating Switch—A simple and efficient device which will automatically notify the user of the vehicle that he has a flat tire, or one that is partially deflated, the alarm system indicating the location of the particular tire. Patent 1769427. John B. Garside.

Fuel Meter for Automobiles—An apparatus comprising a receptacle with valves in the top and bottom, and a rod operating the valves and a float, whereby the amount of fuel consumed may be measured and registered. Patent 1766262. Claude Simmons.

Auxiliary Water-Circulating Means for Automobile Engines Using Thermo-Siphon Systems—Which will eliminate all belts, pulleys, gears, packing glands or parts that would wear or leak, and their attendant disadvantages, yet possessing a considerable means of boosting the water circulation and be easy to install. Patent 1766408. Robert F. Stephenson.

Brake Equalizer—For four wheel brakesf adapted for ready application to any type o automobile for applying the brakes while at the same time providing for an equalization of the pressure, and the proper force for stopping the vehicle. Patent 1770030. Ray Freeman.

Lubricating System — Comprising tubes leading to the different parts of an automobile, providing a lubricating system which may be actuated by electrical apparatus which includes the ignition switch. Patent 1769258. Coy C. Goodrich.

Signal Arrangement for Automobiles—Which includes a current switch, signal horn, signal lights, constructed in such a way that all signals, optical and acostic, can be separately connected or disconnected by means of one and the same current switch. Patent 1770835. John F. Bolin.

Tourist Car—With the over-all dimensions of an ordinary truck, but providing a relatively large floor space when stopped for camping, embodying indoor and outdoor sleeping quarters, comfortable transportation for travelers, convertible articles of furniture adaptable for various purposes, and observation quarters. Patent 1771911. Harry W. Bernecking.

DRAFTING

Learn at Home

DRAFTING is one of the best professions a young man can choose because it pays good salaries and it is the stepping stone to even better positions. Many leading architects, mechanical engineers and electrical engineers got their start at the drafting board.

There is no easier way to learn Drafting than through the home-study courses of the International Correspondence Schools. The practical value of these courses is shown by the success of I. C. S. students and also by the fact that employers are constantly writing us for trained men. We receive more calls for I. C. S. draftsmen than for graduates of any other course.

F. E. King was "a poorly paid clerk" when he enrolled for the I. C. S. Drafting Course. By study, industry, and perseverance he became Chief Draftsman of the U. S. Steel Furniture Company, of Syracuse. He is now earning more in a day than he used to earn in a week.

A. J. Hutchins became Chief Draftsman for the American Strawboard Company and increased his salary 300%—also as a result of I. C. S. training.

There is no doubt that Drafting offers a real opportunity to ambitious men and it will pay you to investigate it. Just mark and mail the coupon and we'll gladly send you a booklet telling all about the I. C. S. courses in Drafting or any other subject in which you are interested.

Vol. 143, No. 4. Price 35 cents a copy. $4.00 a year. Postage prepaid in United States and possessions and foreign countries where eighth zone rates apply. Other foreign countries $5.00 a year, postage prepaid. Canada $4.50 a year postage prepaid. Illustrated articles must not be reproduced without written permission. The use of Scientific American articles or quotations from them for advertising and stock-selling enterprises is never authorized. "Scientific American," registered United States Patent Office.

ACROSS THE EDITOR'S DESK

WE were chatting with the editor of another magazine the other day, as together we glanced through the advance page proofs of the feature articles in the present issue. "Why," he asked, "do you place so much stress on industrial subjects in the Scientific American?" "Because," we replied, "industry today is the child of science. Without science, there could be none of the vast industries that are scattered throughout the world. Men of science, in both the pure and applied branches, are constantly bringing to light new facts that make possible new industries and bring about radical improvements in the old ones. Therefore, we keep our finger on the pulse of industry and report its progress, hand-in-hand with science."

And in our answer to the friendly question will be found the why and wherefore of our annual Industrial Number which you have before you. On the surface, the layman may not see the closely woven connection between science and industry. But when he is taken behind the scenes and is shown how industry profits rapidly by the advantages offered by scientific research, he begins to realize the parentage of our so-called Machine Age, and therefore ordinary factors in our daily life take on a new interest.

One of the most significant articles in this issue deals with natural gas, a fuel that is coming into wide use in both industry and the home. Here is a subject that proves most aptly the point which we made above. Natural gas has been known for centuries, but only recently has it started to climb to a real position of importance in affairs of the world. And science is the factor that has provided the basis for this climb, by making transportation of the gas commercially practicable.

Waste, the bug-a-boo of many industries and businesses, is rapidly succumbing to the advance of research. Many manufacturing plants are finding that waste material which was formerly going up in smoke or down to the city sewer can be reclaimed and turned to profit. Science and industry again. Several phases of this work are described on pages 378 and 379.

The business of making motion pictures grew from infancy to a flourishing adolescence within the space of a generation. Then came a period of partial stagnation. For years, inventors had been working on methods to give a voice to the silent pictures, and at a critical point in that period of stagnation, synchronous recording of pictures and sound stepped from the laboratory and revived the entire movie industry. Today the talkie has largely replaced the silent motion picture, but it still has its defects. These are dealt with, and suggestions for improvements made, on another page.

As these pages go to press, we are starting to work on some of the articles which will appear in the December issue. Prominent among them will be one on another phase of Scientific Criminology, by Stanley F. Gorman of the New York Police College, whose first article on this subject, in the October number, aroused so much favorable comment. In the coming dissertation, Mr. Gorman conducts the reader through the ramifications of a murder inquiry, and clears up many erroneous impressions that the public has regarding police routine.

"Blind" flying may seem to be in the class of useless "stunt" flying until the layman realizes that the underlying purpose of instruction in this work is really to prepare the pilot to meet adverse conditions of visibility that are likely to be encountered at any time, even during short pleasure flights. The development of highly accurate instruments which tell the pilot all he needs to know, without the necessity of actually seeing the ground, has made possible rapid strides in safety in flight. "Blind" flying will be dealt with in a comprehensive manner in an article now ready for release.

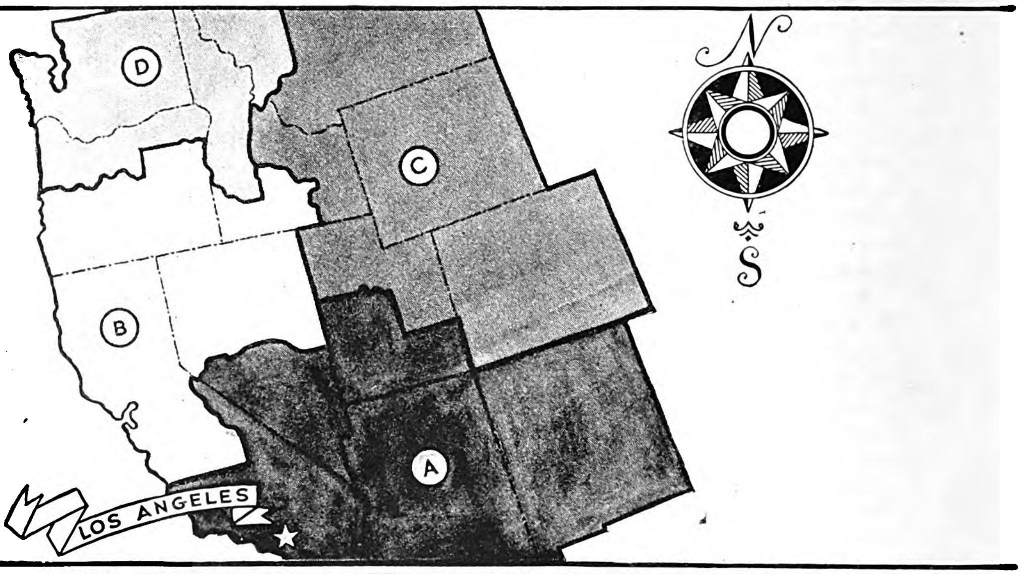
If you are a manufacturer or inventor, you will not want to miss the descriptive article on a testing laboratory where the characteristics of anything from pins to refrigerators can be determined accurately for you. And if you are a consumer, you will be glad to see how your interests are protected in many cases by the exhaustive tests made in this modern "fault finding factory."

These are just a few of the high-lights that catch out attention as we go over the December schedule. Space is reserved for timely articles—spot news—that come up as the constantly changing panorama of progress unfolds. We also have ready for use articles on the new Raman effect in physics, crude oil, "What is a Quantum?" by Paul R. Heyl, the Mayas of British Honduras, X-ray "fingers" that reveal atomic structures, feeding the crew of a battleship, and other equally absorbing subjects.

Orson D. Munn

Western Market

12 Million People



— served most economically from Los Angeles County

There is a distinct freight advantage in serving the Western Market of 12,000,000 population from Los Angeles County... its largest metropolitan center.

Zone A —Population 3,982,582... Local market immediately tributary to and including Los Angeles County.

Zone B —Population 3,002,753... Local market.

Zone C —Population 2,239,483... Parity in freight rates enjoyed by Los Angeles County.

Zone D —Population 2,598,129... Served from Los Angeles Harbor by regular steamship transportation, at low freight rates.

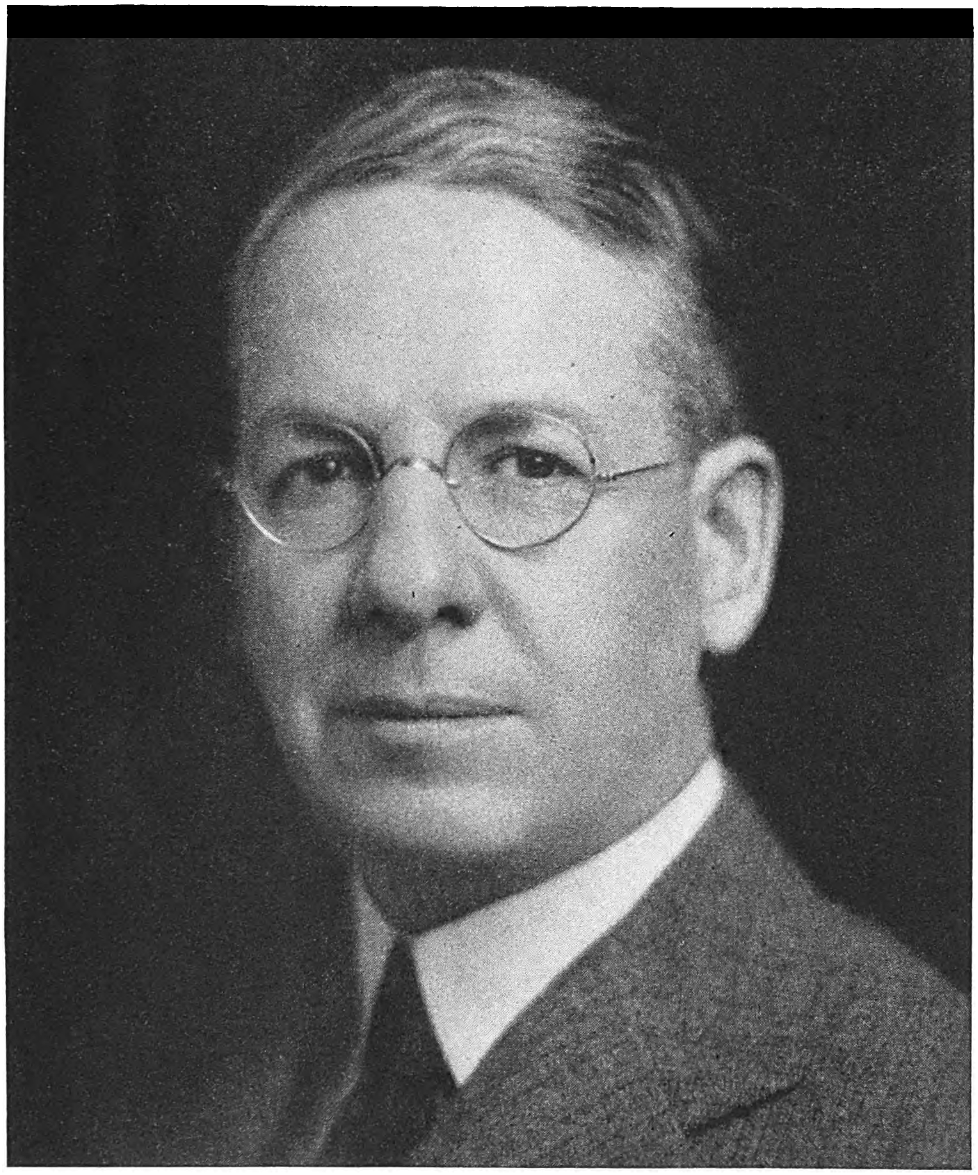
Truck haul delivery is made direct by manufacturers in Los Angeles County to three-fourths of the 4,000,000 people in Zone A... at a freight rate advantage so large as to more than offset slight rate differentials via water route to Zone D.

It will be obvious to the manufacturer who wishes to serve the entire Western Market that he can do so at a great saving by locating his plant in Los Angeles County.

Industrial LOS ANGELES COUNTY

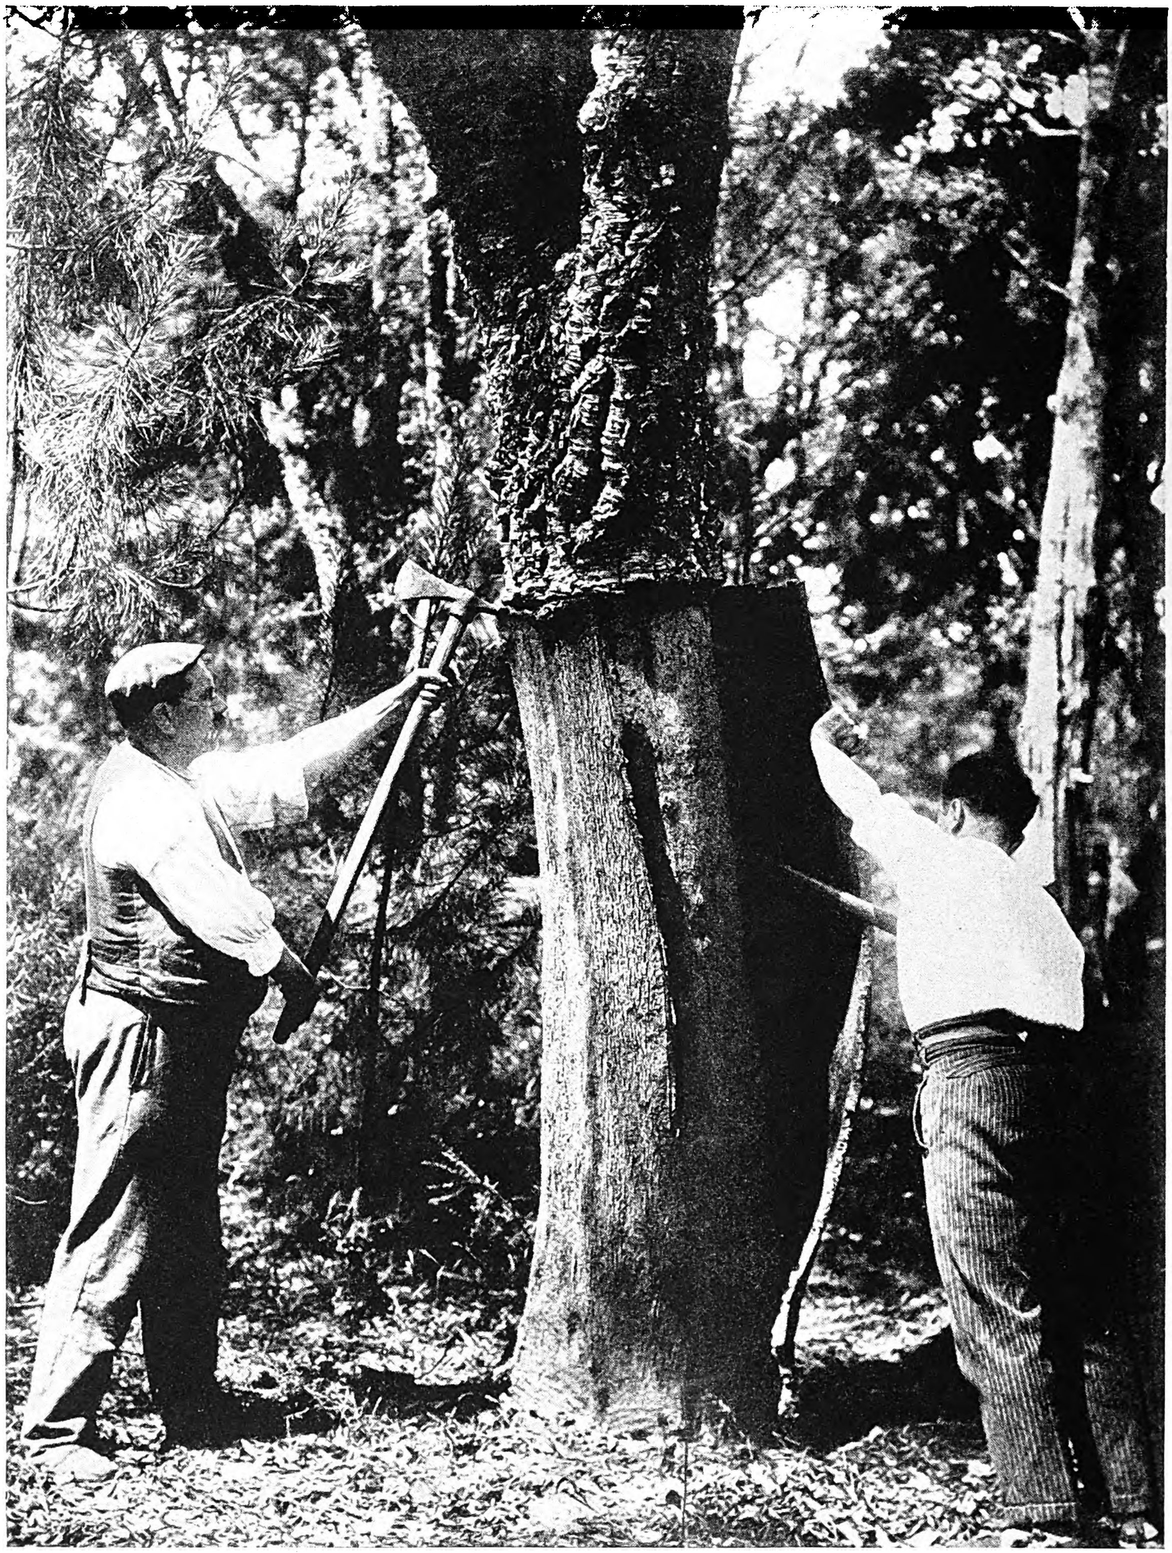
POPULATION 2,199,657

Manufacturing Executives Are Invited to Write to the Industrial Department, Los Angeles Chamber of Commerce, for Detailed Information Regarding this Great Western Market



ANDREW WELLS ROBERTSON

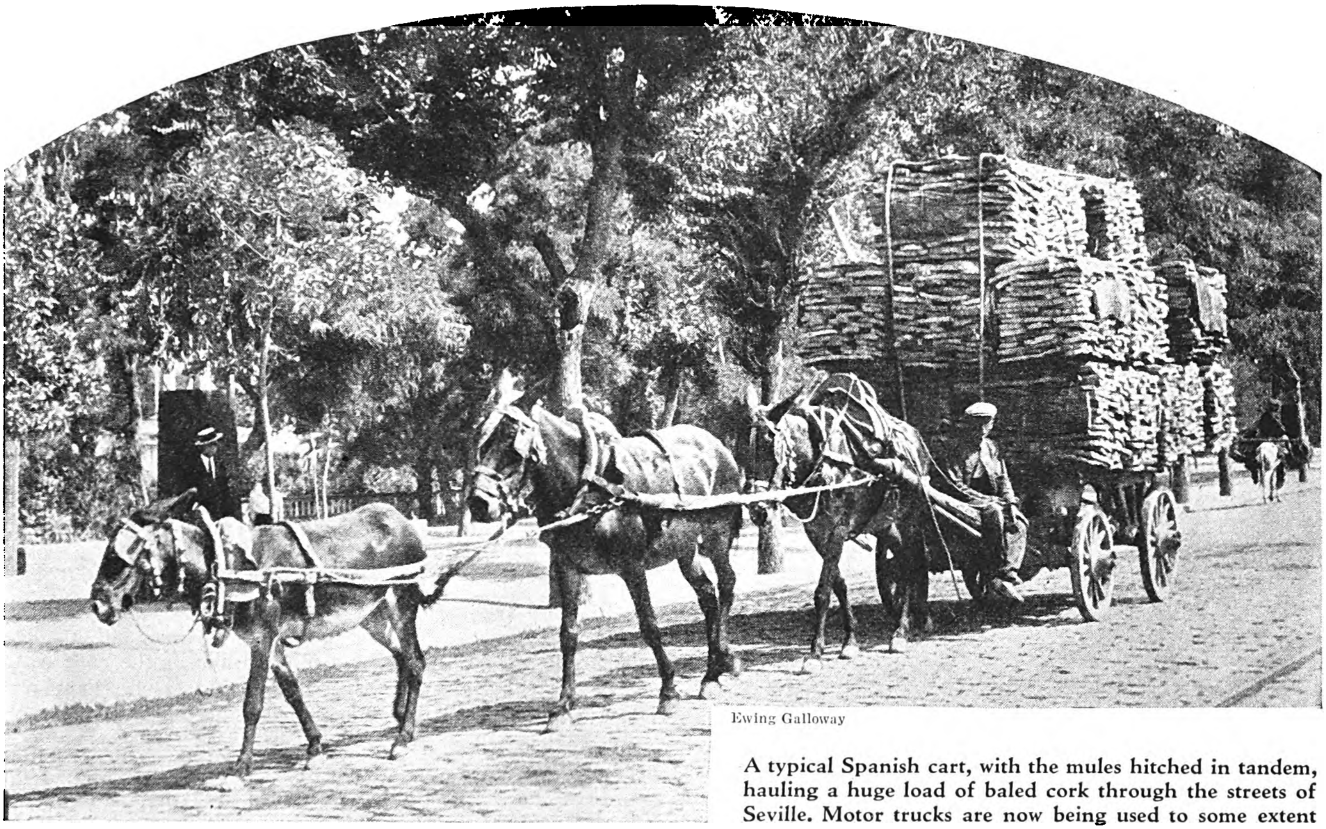
A HIGH SCHOOL principal whose vision saw beyond the confines of school walls and whose understanding of men, fairness, and canny Scot's industriousness have carried him to the high position of Chairman of the Board of the Westinghouse Electric and Manufacturing Company—that, in brief, is the biography of Mr. Robertson. Like many other leaders in American industry, Mr. Robertson's family background is modest. His father, a native of Scotland residing in Panama, New York, was a stonemason by trade. He died when young Andrew was but three years of age but this did not prevent Andrew from getting an education. He was graduated from Allegheny College in 1906 and was principal of a high school for a time. He studied law while conducting a private school for boys and was graduated from the University of Pittsburgh in 1910 with the degree of LL.B. Admitted to the bar, he joined a Pittsburgh law firm, practiced privately for a time, and later became trust officer for a large Pittsburgh firm and attorney for another. By 1918, he had become general attorney for the Philadelphia Company, was made vice-president in 1923, and president in 1926. In 1929, he attained his present position with the Westinghouse company. He is a trustee of his two alma maters, a director of many large corporations and associations, and a member of New York and Pittsburgh clubs. Being an able speaker, he is much in demand on public occasions but has never been attracted to politics—he has been too busy for that.



Ewing Galloway

THE CORK OAK GIVES UP ITS VALUABLE OUTER BARK

THE cork tree is stripped, always during the summer, at intervals of about eight or nine years. After the stripping, the tender inner bark is, of course, exposed for some time until a new layer of cork begins to form. For this reason, the stripping is never done when a sirocco is raging, for the heat of the wind would cause undue drying. In the illustration, an expert cork harvester is shown cutting the bark at the legal height—this must be done very carefully so that no injury is suffered by the inner bark—and his helper is prying off the bark with the handle of his axe. In some localities, the larger limbs are also stripped, but this is not the general rule.



Ewing Galloway

A typical Spanish cart, with the mules hitched in tandem, hauling a huge load of baled cork through the streets of Seville. Motor trucks are now being used to some extent

THE TREE BARK OF A HUNDRED USES

By BURTON DAVIS

WHEN the dry sirocco sweeps up off the Mediterranean and blows its hot breath on the Latin lands that border it to the north, there is one tree that remains gayly green. When the simoons twist north from the parched sands of the Sahara and whirl across Algeria, Tunis, and Morocco, one evergreen oak flourishes. That tree is protected by nature with a thick layer of the finest natural insulation in the world: you know it as cork.

All woody plants have a coating of cork, but this one sort of oak has more than any other. Certain elms and birches elsewhere in the world have outer bark that resembles it, but theirs is comparatively useless to man. The outer bark of *Quercus suber* and its almost identical cousin, *Quercus occidentalis*, known as the cork oaks, is in many ways unique in nature and invaluable in human industry. Nothing natural nor artificial has yet been produced to compare with it, for the *Quercus* bark has seven properties: resistance to the passage of moisture and liquids, buoyancy and light weight, resilience and compressibility, ability to absorb sound and vibration, strong resistance to progressive deterioration, low conductivity of heat, and an uncommonly high coefficient of friction.

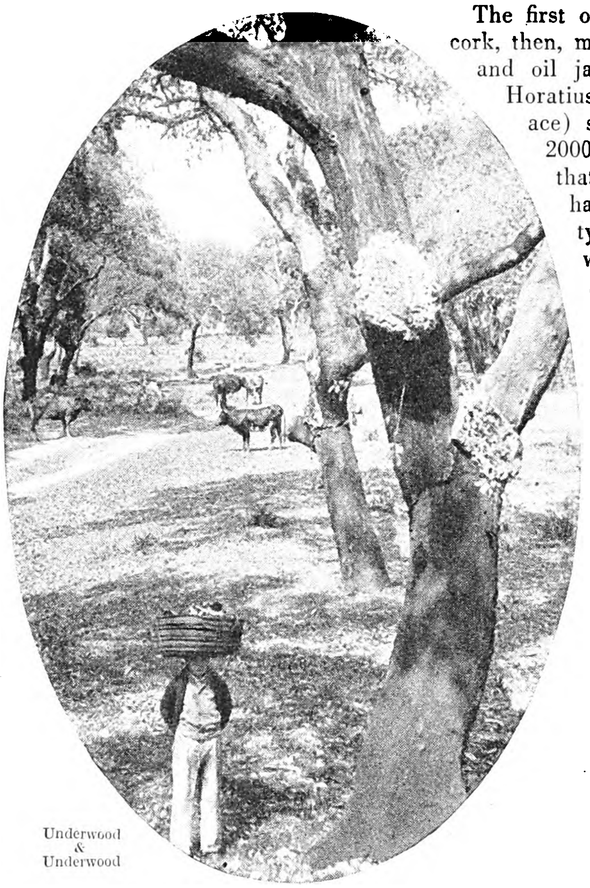
Through at least 2300 years, these properties have successively been discovered and utilized by man. Yet, although cork now has more than 150 distinct uses in the complicated apparatus of civilization, little is known about the physiological, physical, and chemical properties of the odd material.

ALL the literature on the subject of cork, including reports of previous research, could be carried in a small brief case. The men who have handled cork throughout the ages never bothered to find out much about it. A dozen chemists and botanists had worked on the problem of explaining how it grew and of what it was made up, but from 1787 to about 1927, had chiefly developed theories that were later discarded.

There was no accurate information on the number of cork trees in the world and how much cork bark they could supply. Man was using a natural resource and might reach the limit of its supply. Reforestation of cork oak had been largely left to nature and rare private enterprise. Culture of the cork oak was not fully understood. All this had to be studied so that provisions could be made against the future.

And that was what the American cork manufacturers set out to do less than a year ago. Since then another factor has loomed up. Apparently we are about to enter another ice age, this time in food distribution, for huge plants are being built for the quick freezing of meats, fish, vegetables, and fruits to be retailed in packaged form, hard frozen, and kept at sub-zero temperatures. Such low temperatures in freezing plants, refrigerator cars and trucks, storage cases, and household iceboxes will demand cork-board in huge quantities.

Cork, therefore, has rather suddenly become an object of keen industrial interest. The factories called in the research doctors and set them to work to find out how cork is put together, of what substances, and, in exhaustive detail, what its physical and chemical properties and peculiarities are beyond the known and obvious ones. Cork was such a mystery that there was no predicting what they might uncover. To develop a satisfactory substitute for cork is one of the things the scientists hope to do, although at present that



Underwood & Underwood

Cork oaks partially stripped of their valuable bark in a scattered grove at Almorasma, Spain

seems to be a hopeless, impossible task.

In the research and testing laboratories of a large cork company at Lancaster, Pennsylvania, only lately a photomicrographer took the first picture of the individual cork cell. The research, by scientists attached to the company, that led up to the taking of this picture—as well as the picture itself which is reproduced on page 347—showed that the cell has the geometric form known as tetrakaidecahedral.

This difficult word is from the Greek and means "having 14 faces." Lord Kelvin, years ago, found that units of 14 faces solved the problem of dividing all space, without interstices, into uniform bodies of minimal surface. In 1928, Dr. Frederic T. Lewis, of the Harvard Medical School, conducting independent research into cell structure, demonstrated that cork cells are tetrakaidecahedrons, each making contact with an average of 14 others.

EVEN though there are minute interstices between cork cells, these are filled with resin that is impervious to water and most liquids. Obviously a substance, the cells of which fit so snugly, is going to baffle the passage of any fluid which is unable to eat its way through. Thus the word for cork is the word for stopper, also, in most languages—a "stopper" is a "cork."

The first of the seven properties of cork, then, made the stopping of wine and oil jars one of its first uses. Horatius Quintus Flaccus (Horace) spoke of that in Ode III, 2000 years ago. Earlier than that, doubtless, the ancients had used the second property: buoyancy and light weight. Pausanias (not the Spartan admiral, but the traveler and geographer of the 2nd Century, A.D.) recorded that cork bark was used for anchor boards and on fish nets. Since each cork cell is more than half filled with air, the mass is buoyant. Its specific gravity is between .15 and .20, making it one of the lightest of solid substances.

The cell walls of cork are of tough, highly elastic material—much more so even than rubber—hence its resilience and compressibility. At Lancaster a one-inch cube of natural cork was recently put under pressure of 14,000 pounds to the square inch. The sidewise spread under that load was only a quarter of an inch. Released, the cork in a few hours regained between 90 and 95 percent of its original height, while the horizontal edges of the cube returned to exactly one inch. The secret of cork's unique behavior appears to be that only the air in the cells is compressed, hence the lack of side spread and the unequalled regain. Corks jammed in champagne bottles for 10 years will regain three-quarters of their original volume shortly after being withdrawn from the bottle.

Sure-footed burros, top-heavy with huge loads, transport cork in the mountainous sections

Since dead air, in finely divided spaces, is, next to a vacuum, the best insulator known and the poorest conductor of sound and vibration, the fourth and sixth properties of cork are easily explained.

What will keep out heat will, in the popular phrase, "keep out cold"—which means it will keep heat *in.* Hence the use of cork-board insulation, which threatens to outstrip every other use of the cork in a few years, not only to insulate refrigeration units but also to insulate buildings against the winter's cold and the summer's heat. That last-mentioned use may have been the first to which cork bark was put, for the peasants all over the cork oak country still roof and wall their huts with slabs of the crude cork.

THE known chemical inertness—except to a few acids and strong alkalies—of the walls of the cork cell and the intervening resin explains cork's uncommon resistance to deterioration.

The fourth and seventh properties in the list have been the last to be utilized. Cork has only lately come into general use to absorb sound and act as a corrector of acoustics in echo-haunted halls and rooms. The first use in this respect was of cork tile as flooring for libraries and hospital halls. Now whole auditoriums are lined with a fine-grained cork-board. Radio broadcasting and sound film studios are using cork to exclude exterior noises, reduce interior sound and vibration, and break up echoes. Lastly, cork, long applied to reduce vibration and clatter in machinery of a hundred kinds, is now being used in slab form to insulate machines, from light fans to enormous engines and dynamos, against the transmission of vibration and noise.

The seventh property of cork—its high coefficient of friction—has been put to use only since the machine age came in. When cork bark is sliced cleanly, a surface is created exposing tens of thousands of hexagonal open cells to the square inch, each acting as a tiny vacuum cup. This, and the unusual resistance of the cell wall to frictional wear, gives cork the gripping and polishing properties now widely utilized. Plate glass mirrors and windows, fine glass and crystal, and optical lenses are polished on cork wheels. Leather and rubber both wear slick in short order, for their cell material has little of the toughness of cork's mysterious material, called "suber," which is neither cellulose nor wood fiber.

In the Lancaster testing rooms, one-inch squares of cork, belting leather, and rubber, all designed for the same use, were equally weighted and placed on an inclined plane. When the plane was inclined 18 degrees from the horizontal the leather slid down. At 28 degrees the rubber went coasting. Not until the plane was slanting 42 degrees did the cork creep down.

THE temptation in discussing the seven properties of cork is to wander off into fascinating bypaths to tell of the applications of cork that derive from these seven traits. They range from the tiny pieces in the pincers of pince-nez eyeglasses to the acres of cork-board, up to 12 inches in built-up thickness, in the walls of the quick-freezing meat packing plant of 1930; from the cork-lined cap of the tooth-paste tube to the newest and most uncommon use of cork in a planetarium. The first of these in America, recently completed in Grant Park, Chicago, has 9450 square feet of cork-board insulation on the dome.

The story of how and where cork grows, how it is gathered, prepared, transported, manufactured, and used, can only be sketched, for a full description of these fascinating phases would overflow this issue.

With a cork oak acreage of 550,000, Portugal leads the world with a production of 80,000 metric tons of cork; Spain is second with a production of 75,000 metric tons from 637,500 acres; Algeria is third with a production of 27,000 metric tons; while France, Tunisia, Italy, and Morocco come next in order; and even Japan produces about 400 tons of inferior cork yearly.

When part of a grove of cork trees has attained an age of about 20 years—for the first cutting—the expert cutters, each helped by apprentices, start to work. The expert makes a careful cut, with a tomahawk-shaped hatchet, around the trunk just above the exposed roots—in Algeria he may use a circular saw—and another just under the lowermost branches. These he connects with two vertical cuts, following the biggest natural cracks. The assistants help him pry off the bark. All this is done with the finesse of a surgeon, for any injury to the inner bark, or *phellogen,* which builds up the cork, results in a scar area over which no new cork will ever grow. This first cutting of bark, called "virgin" in Spain and "male cork" in France, will sell for a low price, to be used in the rough for florists' baskets, arbors, ferneries, and to be ground into low-grade granulated cork.

Nine or ten years later, the cutters will be back in that same grove, removing the new growth of cork, of finer grain and in every way more valuable. In some places they will also strip the bigger parts of the chief branches; in others, restrained by law or local regulation, they will wait for about five years, strip the large branches, and four years later denude the trunk again. In the French government forests—about half of those in Algeria and Tunisia—stripping the branches is prohibited. In some private forests of Spain the cutters may go back after eight years. In Portugal the law demands a wait of nine years, and the first crop cannot be removed until the tree is 15½ inches around, three feet above ground. Each crop after the first is progressively better until the tree is about 40 years old. Thereafter it may be expected to continue to produce fine cork until it dies, at from 100 to 150 years.

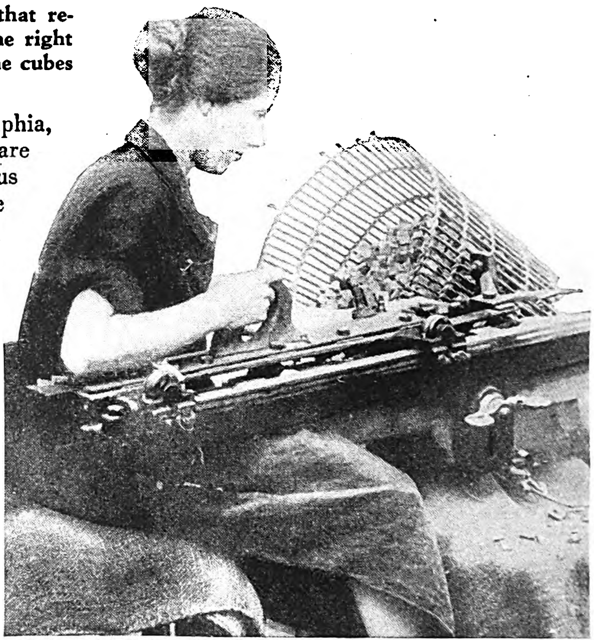
Virgin cork is bought with no particular care, on a weight basis. But from the second stripping on, the value of the cork makes buying a careful balance between buyer's and seller's ideas of its worth. The cork buyer is an important personage, for on his judgment profits are made or lost. He migrates with the cork cutting season, penetrates all manner of country and deals with all manner of cork grove owners, cutting contractors, and government officials.

Arrived at a certain stand of cork, in advance of the cutting season—April to June in North Africa, July and August in Europe—the buyer sends his sampler through the grove on a beeline. With a cylindrical punch, the sampler cuts out a disk of cork from every 5th, 10th, or 20th tree and jumbles these in the huge sack on his back. At the buyer's office these are scrutinized with care, for on the average of them the buyer will base his bidding for so many tons of cork, perhaps for the stripping from a whole mountainside. In the French government forests of north Africa, however, the cork is gathered at stations to be sold at auctions.

To return to the typical scene, say in Spain or Portugal: The stripped cork bark is piled up in the grove and left a few days to dry. Then it is weighed on a "romana," a type of yard scale introduced by the Romans 2000 years ago.

Ewing Galloway

The cork industry in southern France is the same as it is across the border in Spain. Above is shown a girl operating a cork cutting machine that reduces strips into cubes which are later cut into bottle stoppers. At the right a girl is operating by hand a machine that cuts the stoppers from the cubes



Underwood & Underwood

(Cork harvesting methods have changed little in 20 centuries.) The bark is carried on burro back or in carts to the boiling station at the edge of the forest nearest the market or the railroad line.

Boiling the curved slabs in large vats fired with dead corkwood softens the bark so that the rough, creviced, outer layer can be scraped off by hand with a flat tool. This process removes about 15 percent of the weight of the slab, removes the tannic acid from the cork, increases the volume and elasticity, and makes it possible to dry the slab flat. After being roughly sorted for quality and thickness, the dried bark is loaded on sturdy burros, which pick their way carefully down the mountain trails to the railway station, topheavy with a huge pile of the light bark aboard, bigger than the animal himself. As roads in Spain and Portugal are improved, motor trucks are replacing the picturesque burro.

ARRIVED at the warehouse and manufacturing center the crude bundles are opened and the rough edges trimmed off the slabs. Another grading for quality takes place, dividing the cork into about 25 classes. The bark for export is baled in a hand or a hydraulic press, bound tightly with iron straps, and stenciled. The bale is then ready to be loaded into the hold or on the deck of a steamer. Philadelphia, New York, or Baltimore will be the destination of nearly all of the exported crop; the rest will have gone to the stopper cutting shops nearby, the trimmings and "waste" from which will also be baled for export to the cork composition or linoleum factories overseas.

One manufacturing company has its own receiving plant at Gloucester, New Jersey, just below Philadelphia, where the various grades are separated and sent to various plants. At Pittsburgh, where the finer grades are made into bottle stoppers and other natural cork products, the final sorting puts the bark into as many as 80 bins, the grades differing so little that only the expert can detect the difference.

At this point the story of cork divides into four stems: the business of making bottle stoppers and natural cork products; the distinct processes used to make cork composition products out of scrap and grinding grades; the process carried on elsewhere which turns out cork-board for insulation, machinery isolation, and corkoustic; and the complex business of making linoleum, linotile, and other flooring material.

The key to this maze is the utilization of waste. Automatic machines punch bottle stoppers out of the best of the bark. The punched-out strips are ground into flour for linoleum or granulated for making cork composition. The coarser cork is ground into larger granules to be pressed, at high temperature, into cork-board slabs, the natural resin forming the only binder used.

Natural cork is used for pistons for plunger fountain pens and for wind musical instruments; seine and gill corks for fishing nets, and bung corks and artillery practice wads. From natural cork are also made disks for bottle crowns and patent caps, bulletin boards, penholder grips, cork balls for games, plasterers' floats, and many other products.

CORK composition is used for box toes, counters, insoles, heel lifts and pads, and bottom filler in shoes; also, in all manner of gaskets to stop leakage of gasoline, oil, or water; in churn strips, bobbers or floats for fishing lines, and so on.

In the automobile, cork and cork composition may be used in as many as 50 places, most of them unsuspected by the owner.

Linoleum is made from cork flour, as described in the October issue of SCIENTIFIC AMERICAN. Linotile, a tile of linoleum composition, is laid in special patterns by hand and produces marble and tile effects. Cork brick, non-skid, almost impervious and resistant to acids, is used in dairy barns and modern pigsties for better sanitation.

Cork carpet, made of coarser cork, is used particularly in public buildings where sound deadening is important.

Granulated and regranulated cork is used for packing fine china and glass, grapes, and other fruits. Despite modern industrial advances, cork holds its own as one of the most useful of natural substances, although it is still one of the most mysterious after 2300 years of use; in fact, it is playing an increasingly larger rôle in the drama of industrial progress.

OUR POINT OF VIEW

ACROSS THE ATLANTIC

NO transatlantic flight or attempt to make an airplane crossing of this stormy ocean since the unsurpassed flight of Colonel Lindbergh, in May, 1927, has so fired the imagination of the world as the three successful westward flights this summer. A Briton and a German made the first two flights, each with one or more stops, and the climax came when a Frenchman, already famous and a hero among his people, made a non-stop flight from Paris to New York in a plane that was also already famous for its share in his exploits.

In June, Wing-Commander Charles Kingsford-Smith, with E. Van Dyk, Captain J. Patrick Saul, and J. W. Stannage, flew from Ireland to Roosevelt Field, Long Island, in the *Southern Cross*, making one stop in Newfoundland. His flight marked the completion of a spectacular 'round-the-world air trip which had started over a year previously. In August, Captain Wolfgang von Gronau, with Edward Zimmer, Franz Hack, and Fritz Albrecht, made an unheralded flight from Germany to New York Harbor, with stops at the Faroe Islands, Iceland, Greenland, and Nova Scotia. His flight was praiseworthy for two reasons: first, because in this day of blatant exploitation of air feats, his was a surprise trip, few knew anything of it until it was over, and, so far as we know, he has not commercialized it; and secondly, because his route may prove the most feasible when transatlantic airplane services are inaugurated.

When Dieudonné Coste and his copilot, Maurice Bellonte, landed the red *Question Mark* at Curtiss Field on September 2, the final chapter in the long and tragic story of the conquering of the stormy north Atlantic by airplane was written. They had taken off from Paris 37 hours 18½ minutes previously. To these two daring fliers go, therefore, the laurels for the first non-stop crossing of the north Atlantic by airplane from the continent of Europe to the United States. They have accomplished what many others before them had tried and what they had unsuccessfully attempted in 1929.

Aviation owes much to these pioneers of 1930. When and if airplane service is started across the Atlantic to and from the United States, the lessons learned by their flights will have much influence in the choice of routes, modes of operation, and so forth. But we consider that the pioneering has now been completed except in cases where totally different types of planes—such as the Dornier *DO-X*—may be involved, and will frown upon any further individual attempts to conquer the Atlantic. Such transatlantic flights will seem to us to have the taint of commercialism or to be inspired by individual desire to exalt an already inflated ego.

GAS FROM THE EARTH

ON page 380 of this issue we publish the story of the amazing growth of an industry about which little is known: that which has been and is being built up around natural gas. Possessing about twice the heating value of artificial, or manufactured gas, this natural mixture from the earth's reservoirs has been used commercially for over 60 years but has only recently become an industry of huge proportions because of recent technical developments that have shown the way to discovery of large natural gas reserves and have made possible long distance pipe-lines.

During the current year, the natural gas industry has expanded at a greater rate than perhaps any other industry of importance—and that despite world-wide business depression. Its increase in pipe-line mileage from 80,000 to 90,000—including pipe-lines put into operation and also those on which construction has been started—represents an increased capacity of more than 12½ percent. *The Lamport Review* estimates that this 10,000-mile increase adds "at least 250 million dollars to capital investment" in the industry.

Truly this is the bright spot on the business horizon. It puts to shame many other industries that have not progressed this year—yes, despite the depression—and teaches a lesson of research and development, far-sighted belief in the future and rapid expansion. The confidence of the men behind it is worthy of the highest praise.

FUTURE AIRSHIPS

SHORTLY after the successful flight of the *R-100* from Cardington, England, to Montreal, Sir Dennistoun Burney, its designer, outlined a new proposal to establish a transatlantic airship service in which he attempted to prove that a company possessing four or six new ships twice the size of the *R-100* could operate with profit.

Such proposals are not new, but the fact that this one takes such definite form indicates that the time when a transatlantic airship service of some kind will be a commonplace thing draws rapidly nearer. In the face of this fact, American vision apparently does not see as far ahead as does Sir Dennistoun. We have under construction two airships that will be far larger than any heretofore built but beyond construction of these two we have no plans for the future—unless they be deep, dark secrets. And even for each of these two dirigibles, we are importing eight Maybach engines from Germany. This may have no very great significance but to us it is indicative of the passive interest of American engine manufacturers in the development of American airship engines.

One of the many criticisms of the dirigible is that it is bulky. True, but *The Engineer* (London) points out that its weight per passenger is only 1.56 tons as contrasted to nearly 24 tons per passenger of the liner *Mauretania*. Fuel consumption is not considered excessive; and transatlantic passenger and mail rates little in excess of steamer rates are to be expected.

But aside from all such arguments, the airship is with us and we believe it will stay, although no one can predict its ultimate status. Why, then, American apathy toward developing it to the fullest extent? Much experimental work is yet to be done but we should like, particularly, to see some intensive research done toward developing an American airship engine.

INTERNATIONAL AFFAIRS

Navy Day

OCTOBER 27TH, Theodore Roosevelt's birthday, is Navy Day, and at every Navy Yard and on every man-of-war the Navy personnel will be at home to the American people. All who can should take the opportunity to visit the nearest ship or station, to show their interest in the officers and men who are our first line of defense.

In time of war we lavish praise on our Navy; in time of peace we are too likely to forget it. We take the efficiency

RADIO CHARTS THE UPPER AIR*

By JEROME D. VAN BRAKLE

SIGNAL CORPS engineers of the United States Army have devised a means by which radio can be used to determine air conditions several miles above the surface of the earth, and after more than seven years of experimentation they have perfected, at the Signal School laboratories at Fort Monmouth, New Jersey, equipment by which the direction and velocity of the winds at high altitudes may be computed with a high degree of accuracy regardless of visibility.

Visual observations of upper-wind conditions are impossible at night and when visibility is reduced by low-lying clouds or fog. Since many war operations are carried on behind smoke screens or after dark, it became necessary to devise a method of obtaining the desired upper-air information under these conditions for Army use. The radio method was the answer to the problem.

THE radio device, perfected at Fort Monmouth, consists of a miniature continuous-wave transmitter which is sent aloft by means of three hydrogen-filled balloons. Its flight is followed with a loop direction finder, a process known as "tracking" or making a "balloon sounding." Long research was necessary before an efficient direction finder was perfected, as it was found that the commercial instruments used in radio compass work were not sufficiently accurate for meteorological use.

The loop direction finder consists of a specially-built radio receiver of rugged construction connected to a loop antenna composed of a single tube of copper, mounted on a tripod base. To the shaft of the loop is connected a calibrated dial, graduated in degrees and fractions. This dial is used to measure the angles through which the loop turns. Except for the fact that the receiver is of the regenerative type, Signal Corps authorities refuse to divulge the details of its construction.

The transmitter which goes aloft with the balloons is compact and sturdy and weighs less than a pound. It consists of a small vacuum tube, an inductance coil of enameled wire, a small transformer, and a small flashlight battery, the whole outfit costing about five dollars. When the battery is snapped into place at the bottom of the device, continuous-wave oscillations are started which will continue for more than two hours. This wave has been picked up from a distance of 15 miles.

The length of wire which connects the transmitter to the balloon cluster acts as an antenna. Signals are sent at a constant frequency of 2300 kilocycles or 130.5 meters.

When the balloon cluster, carrying the transmitter, is liberated it ascends vertically, because of the hydrogen gas, but at the same time it is blown about by the winds it encounters. This lateral motion is recorded by observers and from the data obtained, the speed and direction of these winds may be accurately determined.

It has been found that the cluster will rise at the rate of approximately two hundred yards a minute and that this rate of ascension will continue until the internal pressure of the hydrogen gas exceeds the outer pressure of the rarefied atmosphere and one or more of the balloons burst. Usually only one bursts and then the others act as a

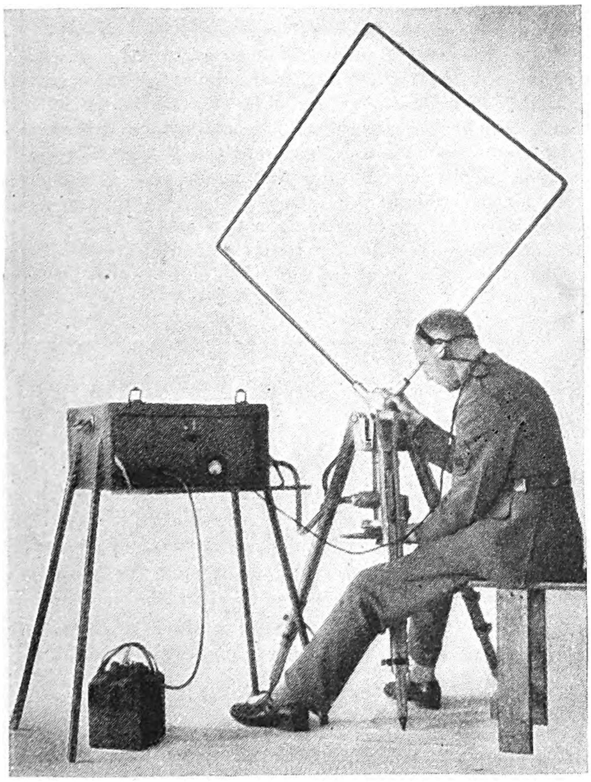
parachute and gently lower the apparatus to earth with little damage.

While the balloons are in flight, observations are taken by two direction finders set up on a base line of known length. Experiments have shown that this length should be three miles for the best results, although shorter distances have been used with a high degree of accuracy. Sometimes three instruments are used; then they are set up in the form of an equilateral triangle of known sides. The third instrument, however, is used principally as a check on the others.

AFTER the release of the balloons, operators obtain bearings on them every minute. Accurate time is given by a clockwork device which emits a howl at the end of each minute and a warning buzz ten seconds before the minute. The bearings are telephoned to an observer at a plotting board where they are entered on a scale map. The point of intersection of each set of two bearings shows the exact position of the transmitter at any minute. From these data it is simple to determine the horizontal flight of the apparatus and by means of a special protractor and a wind scale, the required velocity and direction of the wind at each level of altitude is computed. Balloons may thus be tracked for several miles.

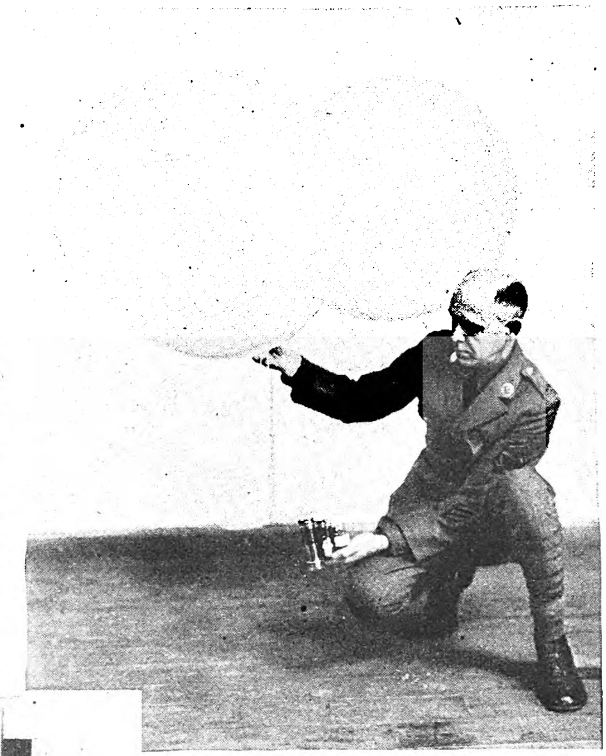
The observers at the loops base their calculations upon the zero point, where the signals from the transmitter are not heard. The loop is revolved until the signals disappear and the angle is read from the scale on the shaft of the loop.

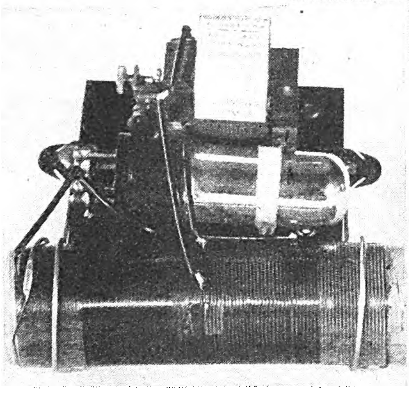


The direction-finder loop in use. The operator swings the frame, listens to the signals, and reads the angle

At the zero point, the plane of the antenna is at right angles to the direction of the transmitter. One of the points of high efficiency of the Army receiver is that the zero point does not vary until the transmitter is more than three miles from the receiver, then the variation is so small that accurate results may be obtained for seven miles and usable results for several miles further. Experiments have shown that the zero point in commercial sets splits before the transmitter is a mile away, greatly lowering the efficiency.

While the new system was undergoing preliminary tests at Fort Monmouth, simultaneous readings were made by radio and visual methods. These experiments showed that the radio method gives more accurate results as the continuous signal can be more easily traced. The visual method is more commonly used, however, because of the greater distance possible and because of the economic phase.





Above: The one-pound short-wave transmitter attached to balloons. *Left:* A close-up of the transmitter. The battery is behind the instruments

In the Atlantic seaboard states, where the prevailing winds are easterly, most of the instruments sent aloft are lost in the ocean, but in the Middle West, 95 percent of the transmitters are recovered. To insure the return of as many of the transmitters as possible, a notice is attached to the set offering a small reward to the finder if the instrument is sent back to the base station.

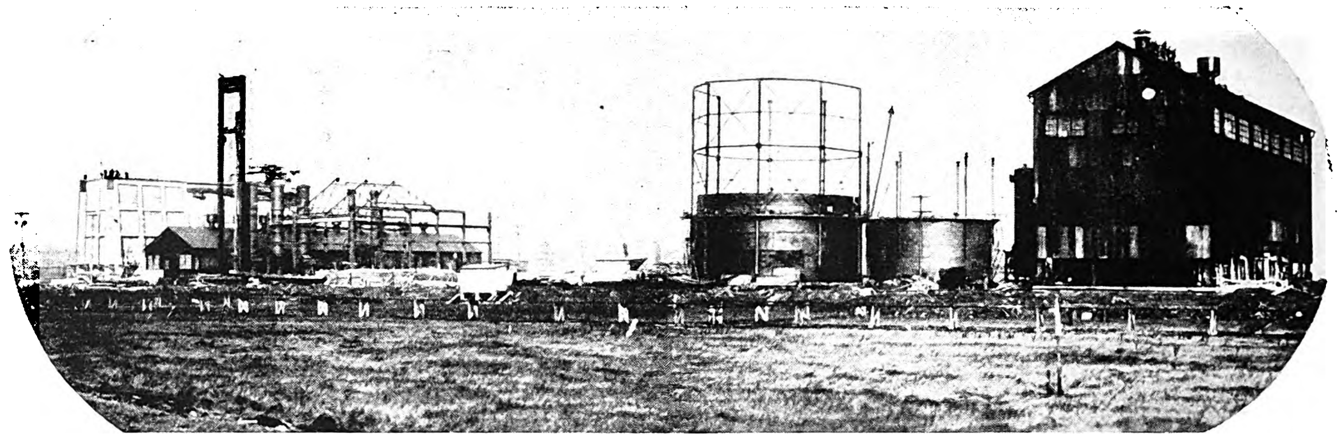
At Fort Monmouth, one day recently, a farmer drove up to the reservation in a dilapidated farm wagon. He walked up to the meteorological officer and handed him one of the transmitters which had fallen on his farm.

"You came mighty near not getting this contraption back," he declared. "When it came fluttering down in my cornfield I thought it was some new kind of bird and I almost wrecked it with my shotgun."

Although many of the instruments are returned in peace times, few recoveries would be expected in time of war. The cost of the apparatus in comparison with its utility and the value of the information it gives is so small that little thought would be given to the loss.

AT the present time, radio officers at Fort Monmouth Signal School are experimenting to find a method of determining upper-air temperatures by radio. A bi-metallic plate of variable capacity at different temperatures has been inserted in the circuit of the transmitter just described. It is designed so that the wavelength will vary as the air temperature increases or diminishes and these wavelength changes will be noted on the ground by means of suitable instruments.

Now that the common wind vane has been lifted high into the air by means of radio, it is the ultimate aim of these agents of Uncle Sam to use the radio device, with variations, to unfold many other secrets of the upper air currents.



Hydrogenation plant of the Standard Oil Company of New Jersey under construction at Bayway

A GALLON OF 'GAS' FROM A GALLON OF OIL

By HENRY W. HOUGH

"OIL DIPLOMACY" is the title of a long chapter in Ludwell Denny's arresting new book "America Conquers Britain" (Knopf), a remarkable record of economic war which is taking place today on a worldwide front in the form of bitter struggle between America and Britain for world markets in major commodities. The struggle takes its most violent form in oil. The most powerful world participants in the great contest are the vast Deterding interests (Shell) of Great Britain pitted against the Standard interests of America. The oil reserves of the smaller nations—Persia, Mexico, Colombia, Venezuela, and so on—are the rich fruits of battle. The accounts of some of the dealings between the rival giants make fascinating if somewhat grim reading; the international oil war is not a game of tiddleywinks. Ostensibly the oil war between America and Britain is conducted by private interests but Mr. Denny reveals that both governments have taken a hand. And why not? Oil is a national asset; without it no nation today can remain a first class power. Britain is not losing the oil war; we are. She has largely outwitted us, gaining control of the best resources. We are left holding the bag. "The public has been in no mood to champion the cause of any oil company at home or abroad," Mr. Denny writes, "but this sentiment is changing. The danger point will be reached when a near-shortage drives prices upward and American automobile owners are told the British have cornered most of the world supply." Britain is keeping much of her own oil supply intact and cleverly finding ways to exhaust ours. The Bergius processes, described in Mr. Hough's article, are German in origin and Standard has obtained them, but the cheapest oil at present comes from the ground. When the American people finally wake up about the oil situation will it be too late?—*The Editor.*

LAST season, or perhaps it was the preceding season, a thrilling drama was witnessed by theatergoers. It involved a young genius who had made a scientific discovery of startling significance. He proved that he possessed the power to blow the world to smithereens. His secret was known only to himself. Anxiety and apprehension resulted—until the closing scene of the play.

Another drama almost equally exciting although somewhat less sinister now is being enacted before a much larger audience. The opening scene was in a laboratory in Germany, and centered about the research of the noted investigator, Dr. Friedrich Bergius. The scientific world was amazed by the news concerning his hydrogenation process for converting wood into coal, coal into oil and gasoline, and so on.

NOW the scene has shifted to America. About a year ago the rights to Dr. Bergius' process were acquired by the Standard Oil Company of New Jersey, in affiliation with the I. G. Farbenindustrie or "Dye Trust" of Germany. With the news of this merger, which followed three years of co-operative examination of the technical and commercial possibilities of the process, there came another startling announcement: "It now is commercially practicable to produce 100 gallons of gasoline from the running of 100 gallons of crude oil, by the addition of gaseous hydrogen under high pressure and high temperature in the presence of certain catalytic agents."

These developments have aroused rather than allayed the fears of those who anxiously await the outcome. Will the next scene show chaos in the petroleum industry? With over-production of oil constantly worrying the producers, must they now face a flood of cheaper "artificial" gasoline?

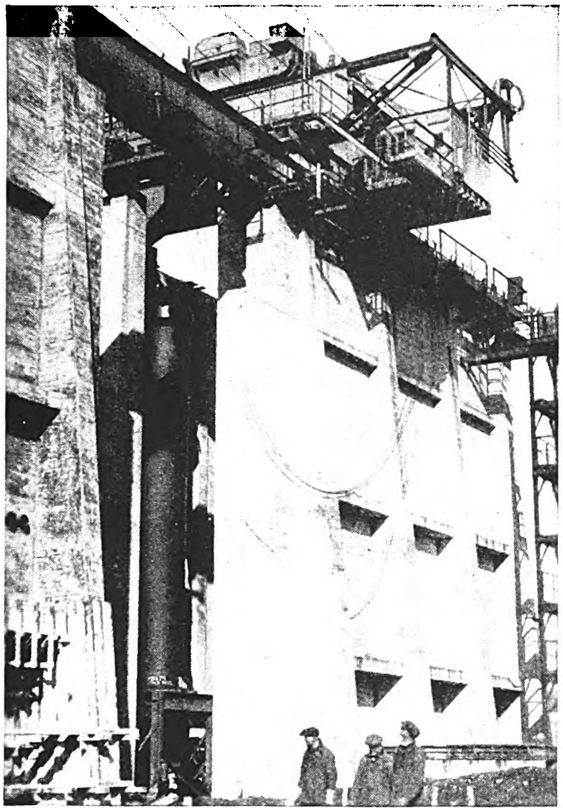
The petroleum industry has waited rather impatiently for further progress reports. The general public has exhibited similar interest, for today "the man in the street" is not only a consumer of gasoline and oil, but also is on the lookout for investments which seem to have great potentialities.

With the opening, a few months ago, of the first of three 5000-barrel-a-day hydrogenation plants, it seems that the Bergius process at last is ready to become an important factor in the petroleum industry The first commercial plant is located at Bayway, New Jersey. Two others are to be built soon, one in Louisiana at Baton Rouge and another in Texas at Baytown. These plants are more than experiments, for each is a large-scale commercial unit based on the results of several years of intensive research and development. No effort has been spared to perfect the conversion apparatus and the methods of operation best suited for commercial production of gasoline and light oils.

To the layman, who may have grown weary of hearing about over-production in the oil industry, it may seem that hydrogenation has been born too soon. Even in the face of solemn warnings that the world's supply of petroleum can last only a few more generations, there are many who feel that at present there is no place for any revolutionary method of producing motor fuels. However, the situation takes on a different aspect when one is familiar with the other great developments which have led up to the present state of affairs.

When the oil industry was very young, there was a well-distributed demand for all of the important products of petroleum. Then the market for illuminating oil stepped ahead of the others. While meeting the demand for kerosene, the refiners found that something had to be done about disposing of the rest of the products.

The solution was found in a new process, by "cracking" the heavier fractions of the crude oils in such a way that a larger proportion of kerosene was obtained. Crude oils which normally yielded 20 to 30 percent of kerosene were made to yield from 50 to 70 percent by this revolutionary step.



The retorts (inside the concrete structure) in which the hydrogenation takes place at Bayway

SOME time later, the situation took a new turn. Gasoline became the most valuable fraction, and the demand for kerosene declined. Again something had to be done about utilizing the less valuable products, and again the solution was found in improving the process. It proved to be considerably more difficult to increase the gasoline yield, but the result was nearly as good as when effecting the decomposition into kerosene fractions. At the present time about one third of the world's total demand for gasoline is met by "cracking" or conversion, rather than by refining.

With this background, it is easy to see where hydrogenation fits into the picture. With the ever-growing demand for gasoline and light oils, there has been constant over-production of the less valuable products, the heavy oils. The market has shown that it does little good to lower the price of this class of fuel. There simply is little demand for it.

Careful examination of the cracking process does not give any grounds for presuming that the problem can be met by an improvement in technique with the present production methods. Attempts are being made to perfect the Diesel engine to so great an extent that it will operate satisfactorily on the inferior grades of fuel oil, as it now does on the better grades. Research in both of these fields is yielding some very commendable progress, but there seems to be no justification for high hopes. Meanwhile, the world has an enormous over-supply of heavy fuel, and the market for the more valuable motor fuels has not yet neared the limit of its elasticity.

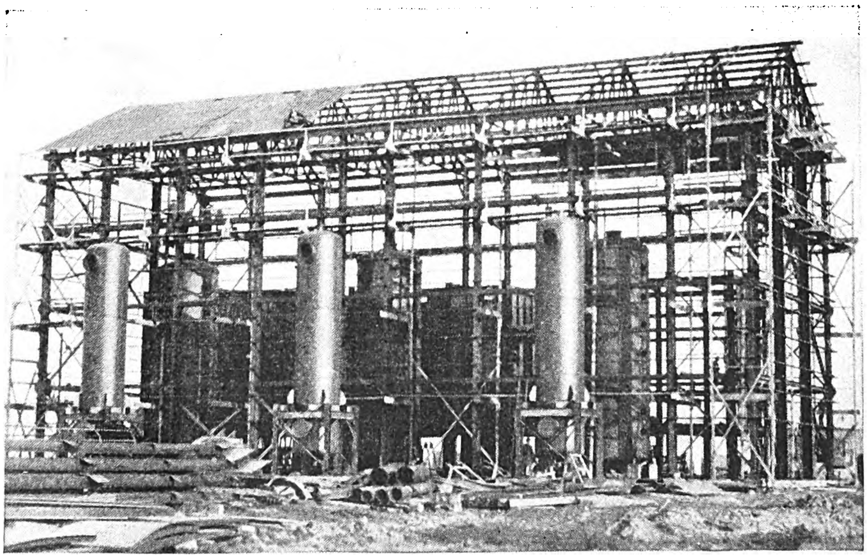
From this it is clear that there is need for a new manufacturing process which can make profitable use of the petroleum products which now are a drug on the market. The hydrogenation process, in its present state of development, is more than capable of meeting this need. This process has shown its ability to do greater things than convert heavy oils into gasoline.

Dr. Bergius took several steps at once when he worked out a method for converting wood into gasoline. First he duplicated nature's "incoaling" process, by which he quickly transformed wood or other vegetable matter into coal. Then he went on with the same process, converting the artificial coal into oil. It was found that the same thing could be done with natural bituminous coal. The hydrogenation of heavy oils into gasoline and light oils is but a page in the story of Dr. Bergius' achievements.

After enumerating that remarkable series of advances, the writer scarcely dares mention Dr. Bergius' one great purpose, an unfinished performance which may yet make these others seem like mere side-shows. Underlying all of his research is the greatest objective of all—to perfect a practical process which will enable man to make his own food, and food for his animals, by utilizing apparently worthless materials which now are burned as rubbish.

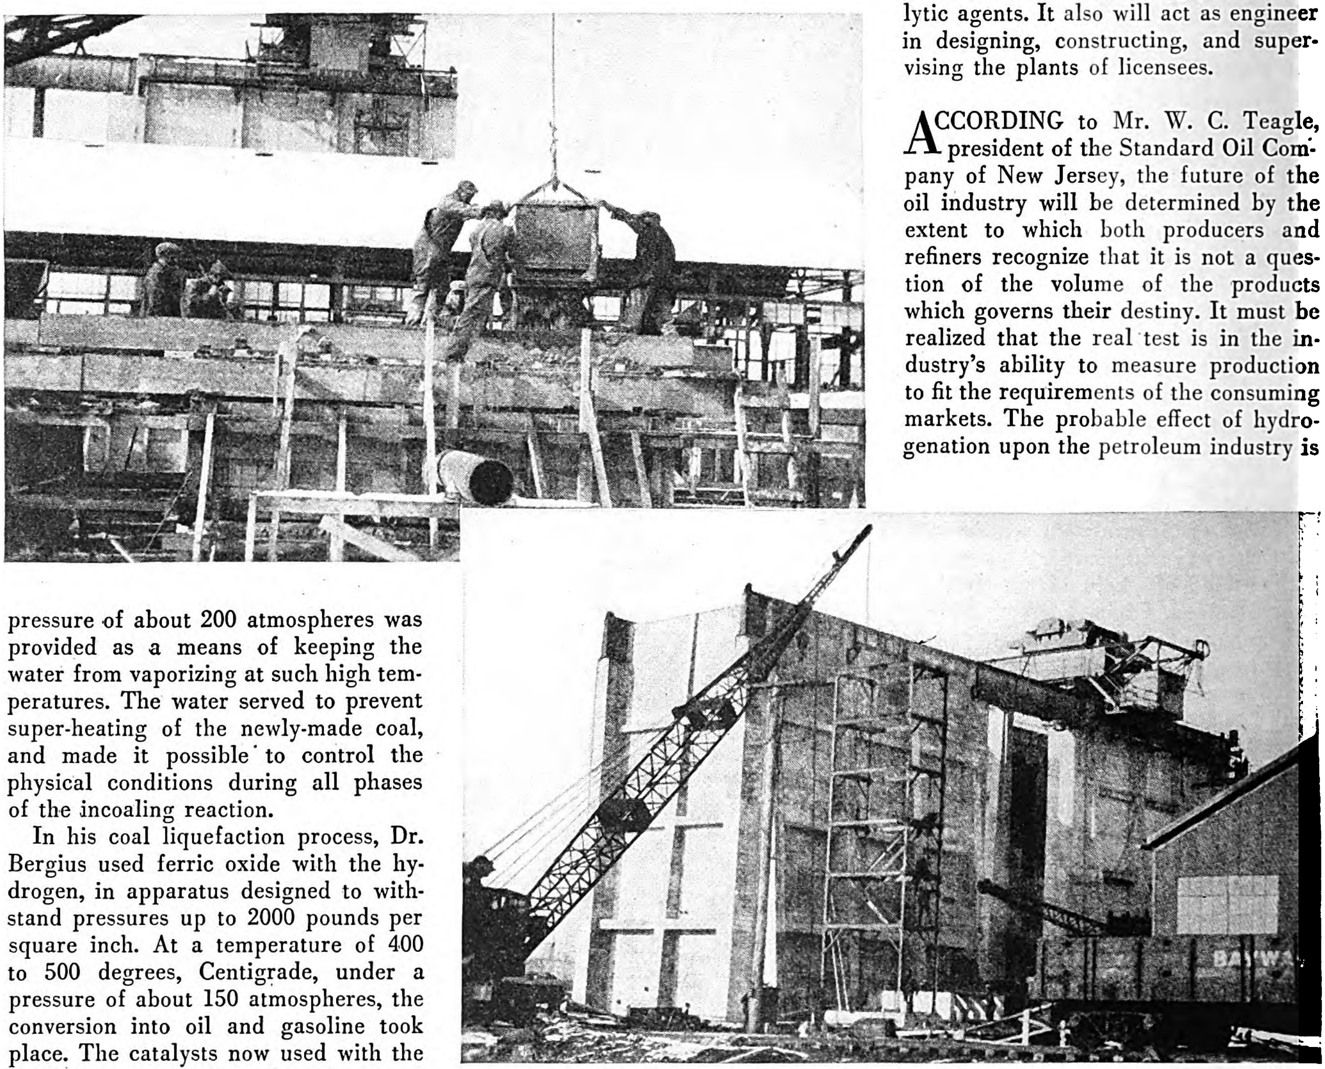
RETURNING to today, after this glimpse of the day-after-tomorrow, we can look more deeply into the process which now is being used to produce gasoline from almost worthless heavy oils. Of paramount importance in this conversion process are the toxin-proof catalysts. These make it possible for the gaseous hydrogen, which is introduced into the high-temperature conversion apparatus under exceedingly high pressures, to transform the molecules of the heavy oils into molecules of gasoline and other light fractions.

It might be well to add a word of explanation about catalysts, for the benefit of those who find the term an unfamiliar one. In chemistry, a substance which serves the useful purpose of stimulating or facilitating a reaction, without adding to or detracting from the



Where the hydrogen will be manufactured—the gas plant building under construction. The new process consists essentially in adding hydrogen to the oil materials involved, is known as a catalyst. In matrimony, a person who plays a similar rôle is known as a matchmaker. In both instances, they may be very helpful.

Years ago, Dr. Bergius effected the conversion of wood into coal, at a temperature of about 340 degrees, in the presence of water in liquid form. A pressure of about 200 atmospheres was provided as a means of keeping the water from vaporizing at such high temperatures. The water served to prevent super-heating of the newly-made coal, and made it possible to control the physical conditions during all phases of the incoaling reaction.



Upper: **Pouring some of the 4700 cubic yards of concrete that went into the Bayway hydro plant.** *Lower:* **Huge concrete slabs enclosing the reaction towers in which hydrogenation actually takes place. Overhead is a traveling crane**

In his coal liquefaction process, Dr. Bergius used ferric oxide with the hydrogen, in apparatus designed to withstand pressures up to 2000 pounds per square inch. At a temperature of 400 to 500 degrees, Centigrade, under a pressure of about 150 atmospheres, the conversion into oil and gasoline took place. The catalysts now used with the Bergius process, as it has been improved for the commercial production of gasoline and light oils, are considered a secret. There also is great secrecy about the exact temperatures and pressures used, and other features such as the design of the high-pressure conversion apparatus.

OTHER investigators, Satatier and Senderens, had found that a nickel catalyst aids in the production of methane gas from coal. The Fischer process of hydrogenation produces benzine by using iron and cobalt as the catalytic agents, and high pressure is not required. In this instance, the catalysts tend to inhibit the formation of methane, and when caustic alkalis are added the conversion continues on down to solid paraffins.

The Bergius process now is being adapted for the conversion of gasoline from heavy crude oils, such as that produced in Venezuela. By present methods of refining and cracking, only a small proportion of gasoline can be extracted from these heavy crudes. Most of the residue is heavy fuel oil, for which there is practically no demand at present.

In the hands of almost any other industrial organization, it might reasonably be feared that the exploitation of the hydrogenation process would bring about chaos in the petroleum industry. However, because of the Standard Oil Company's enormous investment in the oil industry, it is felt that the owners of the hydrogenation process will move with extreme care in order to avoid changing the *status quo* to any great extent.

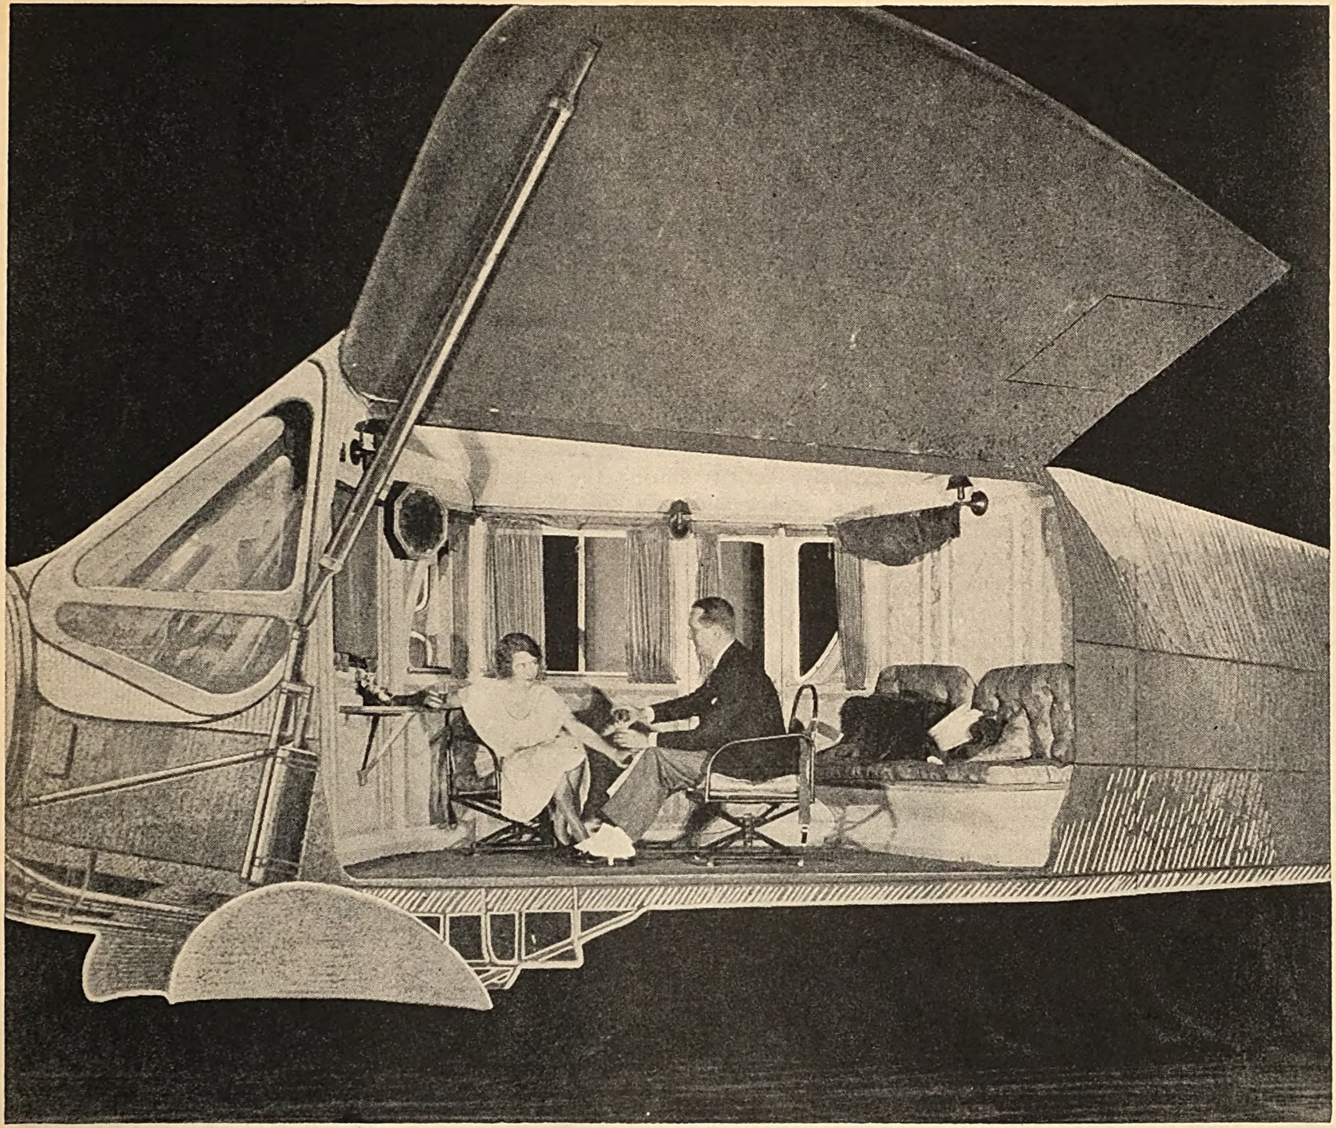
The rights to use the new process in the United States will be leased to other oil companies. Licensing companies will purchase stock in the Hydro Patents Company, a subsidiary of the Standard-I. G. Company, at the rate of one share of stock for each barrel of daily hydrogenation capacity. For example, a firm desiring to establish a plant to produce gasoline at the rate of 20,000 barrels a day will buy 20,000 shares of stock in the Hydro Patents Company.

These outside firms also will be required to align themselves with another subsidiary corporation, the Hydro Engineering and Chemical Company. This organization will furnish the technical information and will supply the catalytic agents. It also will act as engineer in designing, constructing, and supervising the plants of licensees.

ACCORDING to Mr. W. C. Teagle, president of the Standard Oil Company of New Jersey, the future of the oil industry will be determined by the extent to which both producers and refiners recognize that it is not a question of the volume of the products which governs their destiny. It must be realized that the real test is in the industry's ability to measure production to fit the requirements of the consuming markets. The probable effect of hydrogenation upon the petroleum industry is best expressed in Mr. Teagle's own words:

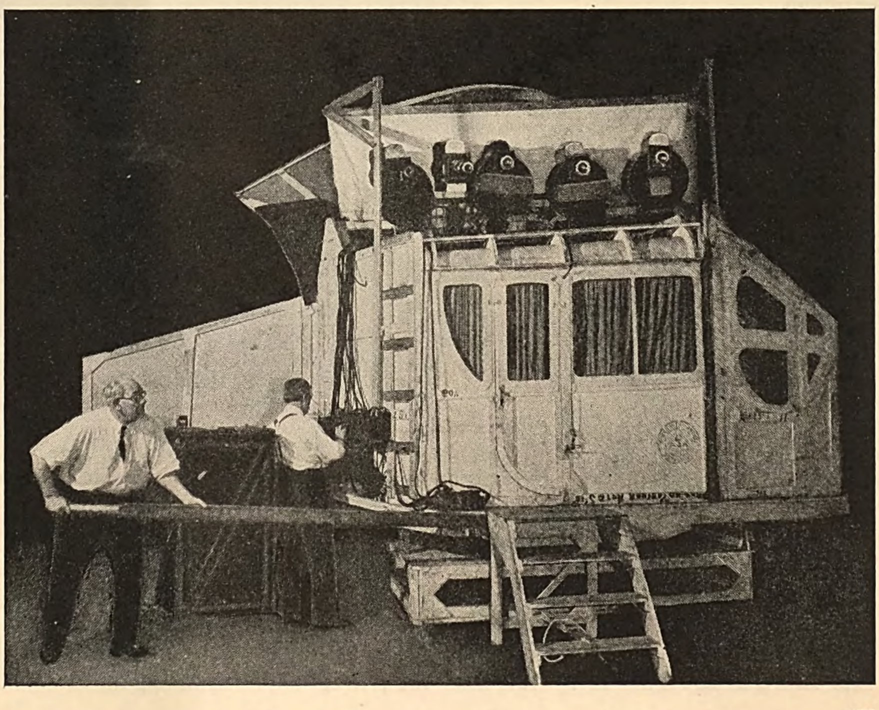
"Through hydrogenation it now is shown to be practicable to convert coal into liquid hydrocarbons at a cost which, although above prevailing oil prices, is not prohibitive. Thus, the coal reserves of the world become supplemental to the crude oil reserves.

"Because of the innumerable new technical problems, solutions of which are required for the practical and profitable use of the hydrogenation method in the oil industry, and because of the relatively large investments required, progress toward its general application will probably be slower than was the case with the cracking development. The ultimate effect, however, should be even more important."



THE STAGE GOES "AIR-MINDED"

ANY play which goes through the hands of David Belasco is sure to be elaborately staged with a fine feeling for detail by this rare artist. His latest production, called "Dancing Partner," has a scene where the lovers are taken aloft in an airplane which cavorts around while fleeting terra firma, clouds, and the starry heavens are viewed through the cabin windows. These illusions are produced by means of projectors carried on the top of the airplane, hidden from the audience by a wing and projecting directly on to the back drop. The electrician controls these effects from the side of the airplane. The huge loudspeaker for the engine effects is located at the left behind the operator who is giving motion to the plane. Another speaker in the dummy cockpit simulates the noise of the propeller and, together with the motions of the landscape and clouds and the sliding passenger seats, serves to give realism to the scene.



EARTHQUAKES

By G. AUSTIN SCHROTER

MANY bizarre theories are prevalent in the popular mind as to the origin of earthquakes and many other unrelated phenomena have been attributed to them, yet they are quite ordinary and commonplace natural processes originating within the outer crust of the earth.

The great Japanese earthquake of 1925 was probably the greatest catastrophe of modern times, and since its advent, Japanese scientists have been among the leaders in seismic studies as well as pioneers in the science of earthquake precautionary measures. Aside from the purely geologic phase of their studies, the Japanese have inaugurated a hitherto undreamed of architectural era in which beauty and safety from crustal movements have been combined.

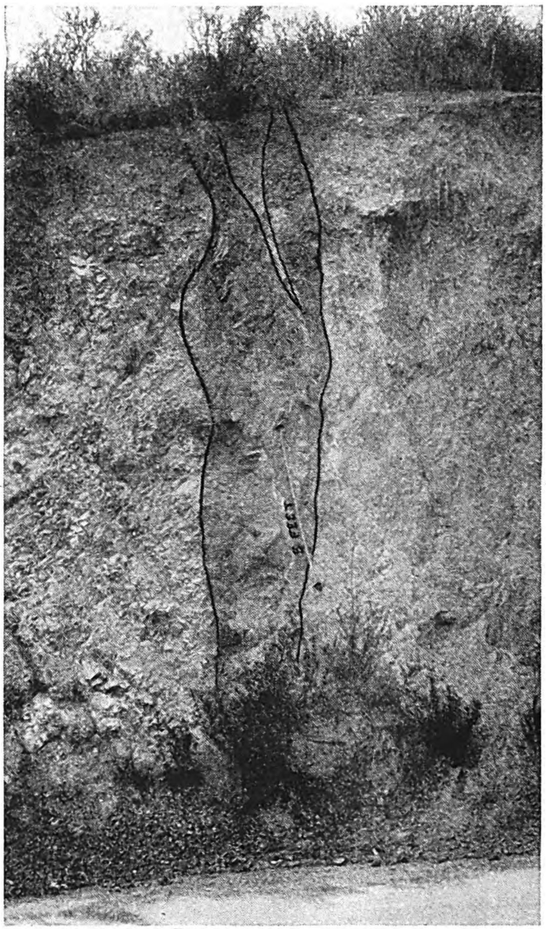
FOR innumerable years scientist and layman alike believed the source of all seismic activity to be in volcanic activity. Although it is quite true that many sharp local shocks owe their inception to volcanic action, in the aggregate volcanism is rather a subordinate cause of major earthquakes.

There are several types of volcanoes whose classification is dependent upon the types of their eruptions.

The quiescent type, of which Mauna Loa and Kilauea in Hawaii are typical examples, completely lack the catastrophic phenomena of the volcanoes mentioned below. The quiet types give rise to outflows of intensely hot lava, without violent projection of gases or solid material; much as a pot of mush will quietly overflow its container and run down upon the stove top. Quite frequently the pent-up lava content will break through the sides of the vent and peacefully roll down the sides of the volcano until it comes to rest on the slopes below. This type of volcano is of relatively slight importance from the seismic standpoint.

The intermediate (Vesuvius) type of volcano stands midway between the quiet and explosive varieties, and quiet outpourings of lava may be preceded by or alternate with periods of violent explosive activity. This is by far the most common type of volcano, and although local tremors may have their birth in this type of eruption, they usually are of unimportant magnitude.

The explosive type of volcano is, as the name implies, marked by violent explosive activity during the eruptive stage, and sudden ejection of gases, dust, and rock fragments is typical. The most outstanding example is Krakatoa, located in the Straits of Sunda near Java. In the eruption of 1883, Schuchert says that "after premonitory outrushes of gas for some time, the great explosion occurred which blew away over a cubic mile of material from the volcano! The vast cloud of ejected material arose over 17 miles into the atmosphere, completely hiding the sun . . . over a vast area. The noise of the detonation could be heard for over 150 miles, and the atmospheric disturbance affected barometers all over the world!"



All photos by R. C. Bowes

A fault showing at a road cut. The black lines were drawn in, as the materials were poorly distinguishable in the photograph. They delimit the zone of crushed, ground-up granite. Note the uncrushed pendant within the crushed zone

Small wonder then, that some violent volcanic outbursts give rise to sharp, disastrous, local shocks. These may be due to the effect of the actual detonation on the surrounding rocks, or they may be due to collapse of the crust due to extravasation of underlying lava, just as a building will be weakened and finally collapse if the foundations are gradually removed. Still another explanation of earth tremors in connection with volcanic activity is the sudden violent shattering of hot rock in contact with steam or cold water. This process is similar to the old trick of shattering rocks by heating them in a fire and suddenly quenching them in water. There is little or no proof for this theory of rock-bursts.

IN the year 1811, the lower Mississippi valley was visited by a series of shocks, many of them catastrophic in magnitude. New Madrid in southern Missouri was demolished, and this earthquake was named after the town. Much of this region is an area of limestone rocks which are relatively soluble in circulating ground waters, as indicated by the many limestone caves which abound in the region. It has been suggested that one of the contributory causes to the New Madrid earthquake may have been the sudden collapse of the roofs of certain of these caverns due to the weight of overlying rock masses. It is, however, obvious that other factors must have entered into the case as the shocks were too heavy and too widespread to have originated in this manner alone.

This leads us to a consideration of the most outstanding and common cause for earthquakes, especially of the more sudden, heavy, and frequently disastrous shocks.

That the outer crust of our old earth is constantly undergoing alteration and modification is a fact patent to the most unskilled of observers. The mighty forces of nature seem to be forever in a state of unrest, and they are constantly at work in their task of altering, shifting, and disintegrating the strongest of rocks and the mightiest of mountain ranges.

The sea reaches eager fingers to the land, and the sea waves with their burden of sand and littoral material wear away the land, under-cutting the strongest of cliffs, and piling the waste material in spits and bars. Tiny drops of rain fall upon the earth and, as each follows the path to the sea, does its finite bit in wearing and transporting the small products of rock decay. Rills, rivulets, and rivers scour their channels and sweep away portions of the banks, ultimately to deposit their load of silt and sand in the ocean or on some lower flood plain. Winds loaded with dust and sand abrade the toughest of rocks and carry the products of the disintegration many hundreds of miles before they are dropped. Glaciers pluck away whole mountains and move them away. Thus, even the mighty continents themselves are in motion! Throughout the vistas of geologic time mountain chains are worn away and new ones are thrown up to take their places. All of nature is at work in the age-old processes of tearing down and building up.

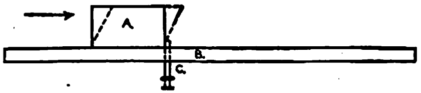
AN attempt to discuss the details of the stupendous forces of mountain making or of the uplift and subsidence of land masses, would require much space, but it becomes increasingly obvious that, when millions of tons or hundreds of thousands of cubic miles of rock are moved from one portion of the earth's crust and deposited upon another portion, adjustment of the crust must ensue to support the gigantic loads thrust upon it.

Every beam, bulwark, or foundation must have an ultimate breaking point when the loads upon it exceed its strength. And so we find that the crust of the earth must give way in places when the load placed upon it exceeds its strength. In short, a rupture or break is bound to occur, and the broken segments in turn will adjust themselves to the stresses which are acting upon them. Such ruptures or fractures in the outer crust along which appreciable movement has occurred are "faults," and it is to them that we must turn in looking for the most common cause of earthquakes.

Proof that the great crustal blocks do readjust themselves to the loads thrust upon them is apparent on every hand. Sea shells and the remains of marine organisms are found on the highest mountains, thousands of feet above sea level, old marine strand lines and beaches are elevated far above the reach of the nearest sea waves. Man-made monuments and temples that were constructed within historical times on perfectly dry land are now found to have sunk beneath the sea and been resurrected, not once, but many times. It does not seem so strange, then, that proofs of this constant crustal unrest frequently manifest themselves as shocks, tremors, and ghostly sounds, apparently arising from the very bowels of the earth.

Movements along faults are constantly in progress. No one region is free from them, and if they happen to occur suddenly or with much friction, they are manifested to our senses, but if the slip be slight or gradual, only the most sensitive of seismographs can detect it.

No hour in the day, no day in the year, and no region on earth is free from earthquakes. They are as common as life itself, but by far the largest number are not apparent to the senses. The idea that any given region is free from earthquake danger is fallacious. In New England, for example, in the 230 years following its settlement, Schuchert says that over 230 earthquakes have occurred.



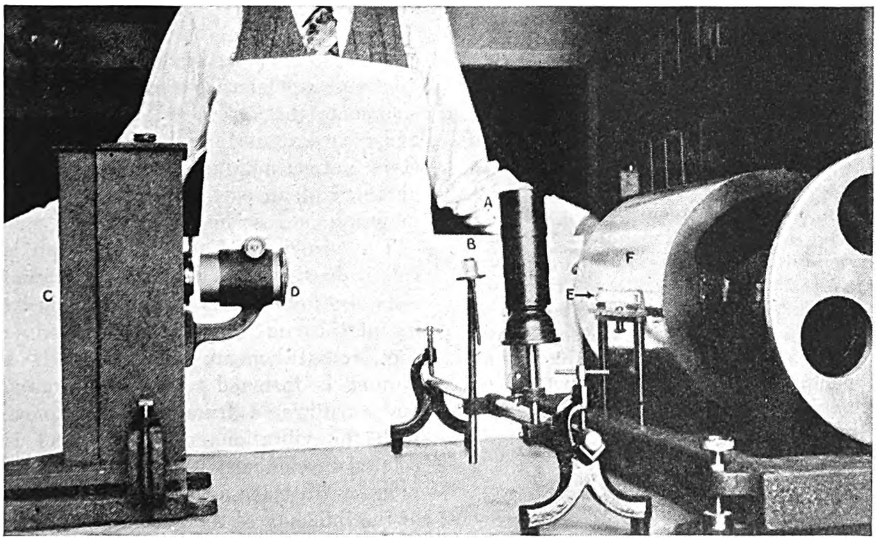
A model to illustrate the principle of elastic rebound. An India rubber block (A) sliding over a table top (B) is impeded by an upward projecting nail (C) until it tends to undergo elastic distortion. If the nail is quickly removed while the force is in operation, the elastic properties of the cube will cause it to snap into its original undistorted shape, causing an "earthquake"

Displacement along faults may be horizontal, vertical, or both vertical and horizontal, the latter being the most common type of movement. One of the most recent theories to be held regarding the origin of earthquakes is known as "Reid's theory of elastic rebound," and it may be explained somewhat as follows.

SUPPOSE that a block of India rubber is moved over a table top, as shown in the figure, until the bottom of the block is intercepted in its movement by a nail or peg driven up through the table. If the moving force continues to act, the top of the block will continue to move forward, but the bottom of the block, by virtue of the obstruction will cease to move. As a result, the elasticity of the rubber block will tend to snap it back to its original undistorted position when the obstruction is removed, and the block will assume its former shape and gliding motion with a sudden snap due to the molecular forces within it.

This process is exactly what may occur in two contiguous blocks of the earth's crust. If they are slowly moving past each other due to the stresses of readjustment, and the movement is impeded by a force tending to stop it, stresses will immediately be set up in the two blocks. The stresses will continue to grow until the moving force or the elastic tendency of the blocks overcomes them, or the rock shatters.

When either of these two phenomena occurs, it will manifest itself by a sudden sharp jar or shock, the intensity of which will depend upon the amount of deformation overcome, and upon the in-



Torsion seismograph perfected by Dr. J. A. Anderson of the Mount Wilson Observatory staff, and Dr. H. O. Wood, Research Associate of the Carnegie Seismological Laboratory at Pasadena, California. A beam of light is sent from the lamp (A) to the prism (B) from whence it is refracted to the mirror of the seismometer within the case (C). The rotating mirror of the seismometer reflects it through the telescopic attachment (D), thence through the cylindrical lens (E) to a strip of light-sensitive paper mounted on the revolving drum (F). The entire apparatus is mounted on a concrete pier within a light-proof cabinet. The optical recording system does away with many difficulties encountered in a mechanical one

tensity of the moving force. The jar will be transmitted instantly to the surrounding crust and waves will be sent out from the point of origin. These are the earthquake waves, and their physical characteristics will determine the amount of damage which they are able to do.

Some faults, quite naturally, are undergoing no movement at present, and are known as "dead-faults." Those which are at present undergoing readjustment are "live-faults." Likewise, some faults are undergoing more rapid readjustment, or are subject to greater stresses, and hence are more pregnant sources of violent shocks.

The great San Andreas rift of California has been studied more in detail, probably, than any other earthquake fault in the world. It has been traced for over 600 miles and forms the boundary between two great crustal blocks, one moving south and the other north relative to each other. It was the San Andreas rift which was the source of the California quake of 1906. In connection with this temblor, it underwent displacement for over 290 miles. Fences and roads crossing it were observed to have been broken and moved apart as much as 20 feet.

MANY earthquakes are due to vertical movement along the source-fault. For example, the great Mino-Owari earthquake in Japan showed a vertical displacement of 20 feet in one place, while the Owens Valley earthquake showed a maximum uplift of 23 feet.

Awe inspiring stories without number have been related by the survivors of great earthquakes, of the fearful sounds accompanying the shock, which were scarcely less terrifying than the quake itself. Tales of unbelievable groaning and grinding noises, of whole forests obliterated, of new streams and waterfalls formed where none before existed, of gaping fissures and dried-up wells, are commonplace and, stranger still, in the aggregate they are true.

For purposes of study, most of the sounds accompanying an earthquake are referred to the Davison sound scale, which is given below:

(1) Sounds resembling wagons, carriages, engines, or trains passing, generally very rapidly, on hard ground, over a bridge, or through a tunnel; the dragging of heavy boxes over the floor.

(2) Thunder; a loud clap or heavy peal, but most often distant thunder.

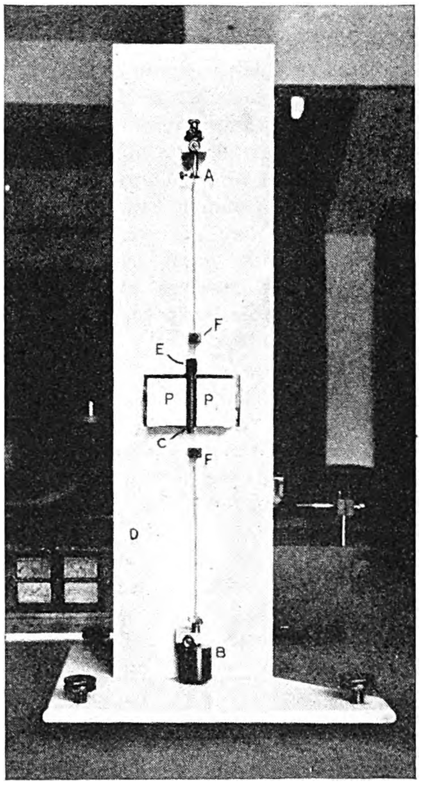
(3) Sounds resembling a moaning, roaring, rough, strong wind, a rising wind, or a heavy wind pressure against the house, a chimney on fire, and so on.

(4) Sounds of great loads of brick, coal, or rock being dumped.

(5) The fall of heavy bodies, banging of a door, pounding of the surf on the shore.

(6) Distant blasting, explosives, firing of artillery.

(7) Miscellaneous sounds such as the roaring of a waterfall, rending or tearing sounds, or the sounds of an immense covey of partridges on the wing.



Enlarged model of the torsion seismometer. A fine tungsten wire is suspended from the screw clamp (A) to the tension attachment (B). A copper cylinder (C) is mounted eccentrically on the wire. When the standard (D) vibrates, the cylinder, due to its inertia, tends to remain at rest. Torsion is set up in the wire causing rotation of the tiny mirror (E) about the suspension. A beam of light can be reflected from the mirror to a sensitized paper on a revolving drum, thus obtaining a photographic record of the shock. A magnetic field from the poles (P) damps the vibrations of the torsion pendulum. The vibration of the wire as a whole is damped by the reservoirs (F) filled with castor oil. This instrument is for use with the horizontal components of the waves. The vertical components are measured in the Carnegie Seismological Laboratory at present, on a seismometer perfected by Mr. Hugo Benioff, Research Associate

The different sounds of the Davison sound scale vary, of course, with the distance of the observer from the source of the earthquake. They may resemble the roar of a train through a tunnel in one place and the low moaning of wind in another. They may be audible to one person and entirely inaudible to another, depending upon the individual's sense of hearing. The author has many times detected the sound of thunder or heavy explosive blasts in connection with seismic activity.

The most outstanding characteristic of these seismic sounds is their extreme lowness or depth of tone, which helps to explain why they may be difficult for some persons to hear. The accompanying sounds owe their origin, of course, to the vibrations set up in the rock by the quake, just as an organ reed vibrates and causes different sounds by different intensities of vibration.

So-called "tidal waves" are another phenomenon accompanying earthquakes, especially in those of submarine origin. These waves have no relation to the tides, but are caused by the elastic rebound of submarine rock masses. In strong submarine earthquakes, the effect on ships is much as though they have struck on a rock or grated over a reef. Seismologists call these vast sea-waves *tsunamis*, from the Japanese, or when they are observed in bays or inlets, as *seiches*, especially when they are stationary waves. They may be as much as 100 or 200 miles from crest to crest, 40 feet high at the point of origin, and they may sweep across the seas with a speed of from 300 to 500 miles per hour. Such *tsunamis* may be unperceived in the open ocean, but upon reaching the land they may pile up as great waves and sweep far inland with great loss of life. Such were the waves that played havoc with Lisbon in 1755, Japan in 1854, and Peru in 1868.

EARTHQUAKES may dislodge loose masses of earth or rock, cause landslides or avalanches, and thus completely denude forest slopes, or dam streams and rivers giving rise to new lakes and "sag-ponds."

The study of earthquakes and earthquake phenomena is seismology, the instruments that are used for detecting and recording earthquakes are seismometers and seismographs, and the record obtained of an earthquake with a seismograph is a seismogram.

The principle of the seismograph is relatively simple. The instrument consists of a heavy mass of metal which by its inertia tends to remain at rest while the ground beneath it vibrates. If a pointer is fastened to the inert mass, and a calibrated drum which will move with the vibrations of the ground is rotated in contact with the pointer, the pointer will leave a record on the drum of the intensity of the shock, and of the frequency, amplitude, and period of the accompanying waves.

The classic example of the seismograph, and at the same time, one which is easily constructed, is a heavy steel ball or bearing placed on a smoked glass plate. If a shock occurs, the ball will tend to remain at rest while the glass plate under it will vibrate to and fro, and a record of the "quake-tracks" will be left on the soot.

The ideal seismograph should be able to record the wave motions in three dimensions; that is, north-south, east-west, and up and down. So far, no such ideal instrument has been devised and in practice it is necessary, if accurate results are required, to use two types of instruments, one for vertical, the other for horizontal components.

The movements of the ground during an earthquake shock may be of two kinds: (1) in large earthquakes, there may be a sudden, large displacement, or a violent lurch of the crust, either horizontal or vertical, or in both planes, or (2) as in all earthquakes, there is a vibratory motion of the ground. The measurement of the former, the great lurches or sudden displacements, can not be accomplished by seismographs. When they take place the ordinary seismographs are thrown out of action or damaged. For recording the vibratory movements, the latter, it is necessary to have two sets of seismographs, one for near, and the other for distant, shocks.

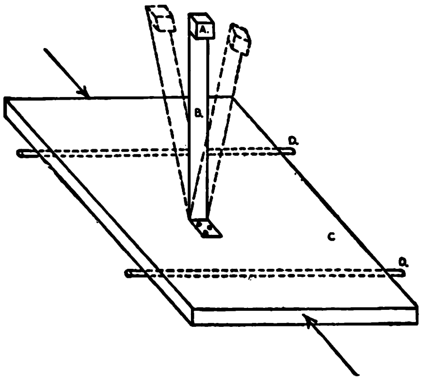
A STUDY of seismograms has indicated that the main shock is preceded by smaller, so-called "fore-shocks," and followed by slighter "after-shocks." The fore-shocks are due to the waves which have taken the shortest path from the source of the temblor to the instrument *through* the earth. The waves of the main shock are those which have traveled *around* the periphery of the earth. After-shocks are usually the result of final readjustment to stresses along the fault. In the Italian earthquake of July 23, 1930, the after-shocks continued for several days after the main, destructive shocks, and did much damage to buildings already weakened.

If three or more stations accurately record the shock, it is a fairly easy matter to calculate the origin of the earthquake. The greatest difficulty is to record the exact time of arrival of the quake at any one station so that the relative time may be determined.

The Seismological Laboratory of the Carnegie Institution of Washington, which is situated at Pasadena, California, is connected with a network of seven recording sub-stations located at Tinemaha, Haiwee, Santa Barbara, Riverside, Pasadena, Mount Wilson, and La Jolla, California. The time of arrival of a wave at any station is co-ordinated with the other stations by means of a dot-dash radiogram from a powerful, long wave, radio station. Thus, if a wave arrives at Pasadena at the beginning of a dash, and at Santa Barbara at the end of a dash, the relative time of arrival between the two stations can be calculated, and the ultimate source of the quake located.

Although, as has been mentioned, no locality is free of earthquakes, certain regions are more liable to dangerous tremors than others. These large well-defined tracts are known as seismic belts. One of them borders the Pacific Ocean, and follows the west coast of South and North America, Alaska, the Aleutian Islands, and the islands off the coast of eastern Asia. The other seismic belt borders the Mediterranean, the Alps, the Caucasus, Himalayas, and so into the East Indies.

The seismic belts follow in general the great zones of weakness in the crust of the earth. For example, off the west coast of the Americas the land is rising with respect to the ocean floor. In regions of active mountain making, great river deltas, rising or subsiding land tracts, and so on, the danger of heavy shock is more imminent.



A model to illustrate the motion in tall buildings or high stacks. The heavy metal bob (A) is mounted on the flexible brass pendulum (B) which in turn is screwed to the base (C). The base is free to roll over the rollers (D). A slight back-and-forth motion of the base will cause the pendulum to swing through a constantly growing arc

In accordance with what has been said regarding the origins of earthquakes, it would seem that in a region where many recurrent slight shocks are prevalent or common the danger of heavy damaging shocks is less. Conversely, in regions of seismic activity, periods of long quiescence may be the forerunners of a violent earthquake.

To the American people, perhaps the most horrific example of an earthquake in the rôle of a destroyer was the great California earthquake of 1906, which resulted in untold suffering, property loss, and a casualty list of close to 1000 lives. The city of San Francisco suffered the greatest loss, due in large part to the destructive fire which swept unchecked over the city following the quake, owing to destruction of pipelines by the tremors.

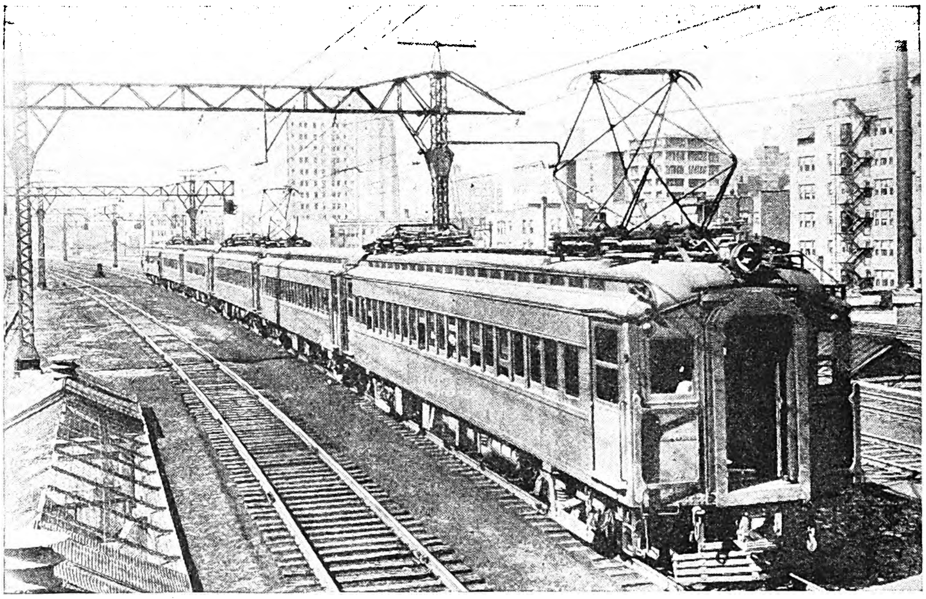
On the 28th of December, 1908, the two cities of Reggio and Messina in southern Italy, were completely destroyed with a loss of life of approximately 200,000 souls. The more recent Italian earthquake of July 23, 1930, probably had its inception in the same region, which is an active seismic one, and had the proper precautionary measures been observed, the loss of life in both of these disasters would have been very greatly reduced. In general, the least risky part of the earthquake cycle is the period after a quake; while the stresses once more accumulate after several years. Yet, such is human nature, much attention is given to precautionary measures at the former part of the cycle, but the least at the later time of increasing risk.

THE greatest danger to the populace during an earthquake arises out of poorly constructed buildings and the tendency to become panicky. By referring to the accompanying figure, the danger to be expected from very high buildings becomes obvious. A high building during a shock may act as an inverted pendulum, so that a very slight oscillation of the ground will be greatly amplified in the upper portions of the structure. Notice a clock pendulum at the point of support. The arc through which it swings is slight. At the bob, however, the arc of swing is greatly amplified, and it is in this principle that the danger from high buildings lies.

In an active seismic region the heights of buildings should be, and frequently are, limited. The danger from falling cornices, high smoke stacks, and perched water tanks can not be stressed too much. In a metropolitan district, it is far safer to run into a Class A building than into the street during a tremor, as the greatest danger lies in falling objects rather than in collapse of walls. Buildings on filled or made ground, likewise are in more danger of collapse than similar buildings built on bed rock.

Movements are now under way, in many of the larger cities, to pass ordinances requiring that buildings be designed to withstand horizontal stresses as great as the stresses upon their foundations. Large buildings, dams, and similar structures should never be built over or close to a live fault, as the danger is imminent. Brick buildings, unless highly reinforced, should be avoided in active seismic regions.

The science of seismology is still in its infancy, so that it is difficult to predict just what strides in earthquake prognostication will be made within the next few years. It is certain, however, that at present, no person can predict the time of occurrence of an earthquake in advance. The old superstitions that earthquakes are more apt to occur during the summer in preference to other seasons, or that they are preceded by "earthquake-weather," is so much rubbish. No good can ever come of such fallacies. They should be relegated to oblivion with the old superstitions of witchcraft and astrology.



Multiple unit cars in service on the Illinois Central in Chicago. Passenger cars of this type are widely used in suburban and urban service

RAILROAD ELECTRIFICATION

By FRANCIS H. SHEPARD

Director of Heavy Traction, Westinghouse Electric and Manufacturing Company

WIDESPREAD opinion has it that automobiles, buses, and airplanes are taking the business of the railroads and that, therefore, they are being electrified for economy's sake. Neither the postulate nor the conclusion is correct. While railroads admittedly are not now operating on a high-profit basis, there is a steady increase in freight shipments and even an increase in long-distance rail travel and far-sighted authorities are very optimistic for the future. Economy has no place in the American scheme of electrification, for the operating economy on electrified American roads is practically nil. Mr. Shepard has, in the accompanying article, given us the truth, as an expert sees it, about rail transportation, its relation to the electrification problem, and the full significance of the latter—what it means to railroads, to the investor in railroad securities (who will read between the lines), and to the country at large.—*The Editor*.

RAILROAD electrification in the United States is entering into an era of increased activity. Several of our railroads are now beginning to electrify their main lines and others are actively considering plans to the same end. The cost of projects at present actually under way exceeds a hundred million dollars, and the total for those contemplated is many times that amount.

Much the same tendency is noticeable throughout the world. All of the nations listed in the accompanying table are either extending or planning to extend their electric service, and, in addition, electrification work is under way in seven or eight other countries.

No single cause is responsible for all this interest. Electricity as a tool for moving traffic has a number of advantages, some of which may be the determining factors in one case while totally different ones may govern in another.

IN many instances, especially outside the United States and Great Britain, the fuel situation provides the underlying motive for electrification. When a nation lacks abundant supplies of first-class coal but is favored with ample waterpower or some form of low-grade fuel, the use of electricity for railroad operation not only may effect a large saving in operating expenses but means independence of coal-producing countries in times of emergency. Switzerland, which has already electrified almost half of her route mileage, furnishes a typical example of this condition, and in the same category are Austria, Brazil, Chile, Italy, Norway, Sweden, and, to a lesser degree, France and Germany.

In this country, on the other hand, where the cost of coal and oil is comparatively low, little or no operating economy would result by saving fuel through electrification; the fixed charges of the electric installation would, in general, be greater than the cost of fuel saved. In the decision to carry out one American electrification—that of the Chicago, Milwaukee & St. Paul—the use of waterpower played an influential part, but all the other installations in the United States were due to other considerations, which can be summarized as follows:

Tunnels. The original application of

IMPORTANT ELECTRIFIED RAILROADS OF THE WORLD

	Electrified Route Mileage	*Total Route Mileage*
United States	2500	251,000
Argentina	68	23,000
Australia	230	22,300
Austria	450	4370
Brazil	251	18,700
Canada	40	40,000
Chile	210	5400
Cuba	155	3800
Czechoslovakia	30	8800
France	875	33,000
Germany	975	36,000
India	150	38,000
Italy	1070	12,000
Japan	200	13,000
Morocco	150	900
Norway	115	2000
Spain	370	9700
Sweden	730	9800
Switzerland	1550	3600
South Africa	200	11,800
United Kingdom	450	24,000

electric power for main line haulage was made in 1895 by the Baltimore and Ohio Railroad for the purpose of avoiding smoke conditions in its long tunnel under the city of Baltimore. The success of this undertaking and subsequent development led to the use of electricity by the New York Central, the New Haven, and the Pennsylvania railroads for their tunnels into New York City, by the Boston & Maine for the Hoosac Tunnel, by the Grand Trunk for the St. Clair Tunnel, and other installations.

SUBURBAN and Terminal Service. The development of the electric street railway and, especially, the use of electrically-operated trains on the elevated railways of Chicago and other cities, showed that electric operation was superior to steam in many respects for heavy suburban service. Electric motor-car, or "multiple-unit," trains accelerate more rapidly and hence can make better time than steam trains, even if the maximum speeds of both are the same; on running into a terminal they can be run out again without further switching, whereas several car movements are needed to reverse a locomotive-hauled train, which not only require time but may congest the tracks outside the terminal; they can run through residential districts without seriously affecting real estate values; and, of course, they can move freely in tunnels of any length.

For these reasons, electric operation was adopted by the Long Island and the New Haven railroads in the vicinity of New York, the Pennsylvania at Philadelphia, the Illinois Central at Chicago, and the railroads around London, Paris, Melbourne, and other large cities.

Mountain Grades. Of a group using electric operation for totally different reasons, the Virginian Railroad is typical. The chief business of this road is to haul coal from West Virginia to tidewater at Norfolk, Virginia. Its line crosses the Allegheny Mountains and at one point some very heavy grades against traffic are encountered. Under steam operation, these grades formed the "neck of the bottle" for the railroad. Even with the use of the most powerful of steam locomotives, traffic slowed down here and the capacity of this portion set the limit to the entire road.

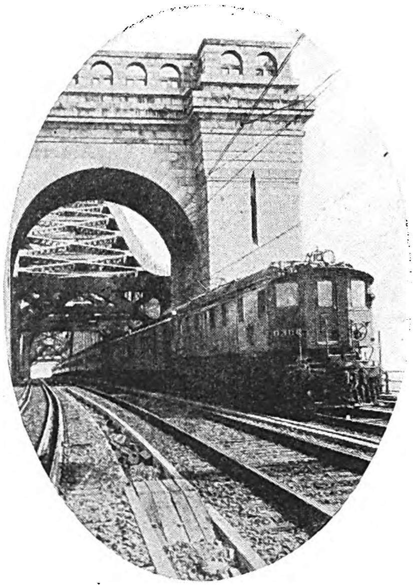
In order to increase this capacity, which was becoming more and more necessary, there were two alternatives: to retain steam operation and increase the number of tracks, or to increase the power for each train by using electricity. Owing to local conditions, the cost of additional tracks would have been exceedingly high, so electric operation was decided upon. Today, locomotives applying at times more than 20,000 horsepower per train are in use on this road, and trains are being moved up the steep grades at twice the former speed. The net result has been to increase the capacity of the road by more than 100 percent, with even greater capacity available if needed.

Other railroads using electric power for mountain-grade divisions include the Norfolk & Western and the Great Northern.

IT is obvious, however, that if these reasons alone influenced electrification in this country, we would see no general use of electric power here. The electrified areas would be confined to the great cities, the mountainous districts, and some special localities, but steam would be employed everywhere else. This, indeed, was the situation until very recently—until, in fact, the Pennsylvania Railroad announced its plans to electrify its entire system of all services from New York to Washington and as far west as the vicinity of Harrisburg, Pennsylvania.

In order to appreciate the full significance of this electrification, which is the most extensive and comprehensive one in the world, it must be considered in relation to our transportation situation as a whole.

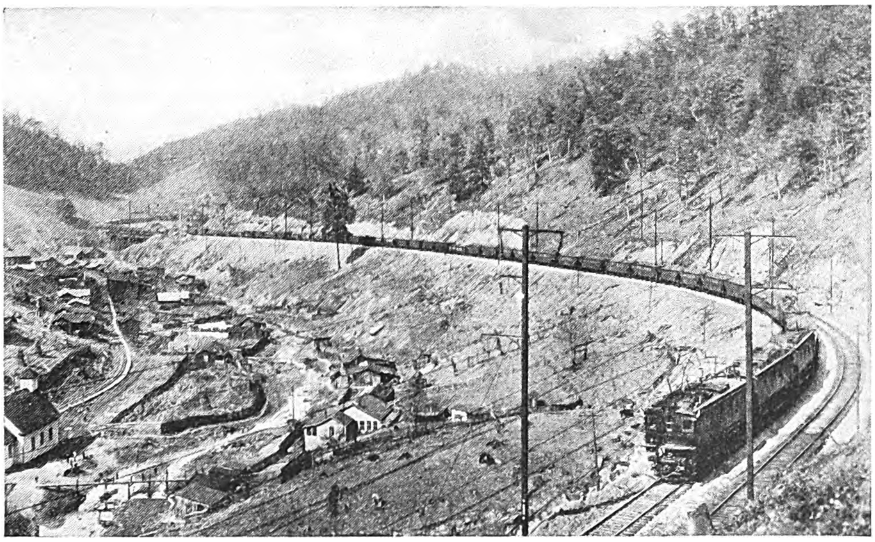
Railroad transportation is vital to the United States. Because of it, our vast territory has been developed and our people have been held together as a single nation. The moment our transportation service fails to meet our needs—as it did during and immediately following the war—everyone suffers: the price of everything we purchase and the cost of everything we produce promptly rise.



Crossing Hell Gate Bridge on the New Haven: The Colonial Express with its 178-ton electric locomotive

OUR demand for rail transportation far exceeds that of any other people. We require 4000 ton-miles per capita, whereas the British requirement is about 500 ton-miles. And this demand has shown marked growth: our ton-mileage for 1900 was 100,000,000,000, and today it is 440,000,000,000; and although with the present trend the aggregate is not increasing, this may be assumed to be only a temporary condition. It is true that a decrease in passenger movement has taken place recently due to the advent of the automobile, but this applies mainly to local and branch line service. On the other hand, there has been a pronounced increase of passengers traveling long distances and between populous centers. The automobile is, in fact, creating traffic by increasing the general movement of our people, by opening up areas for residence which were previously inaccessible, and by making us more travel- and speed-minded. The airplane is also acting in this same direction.

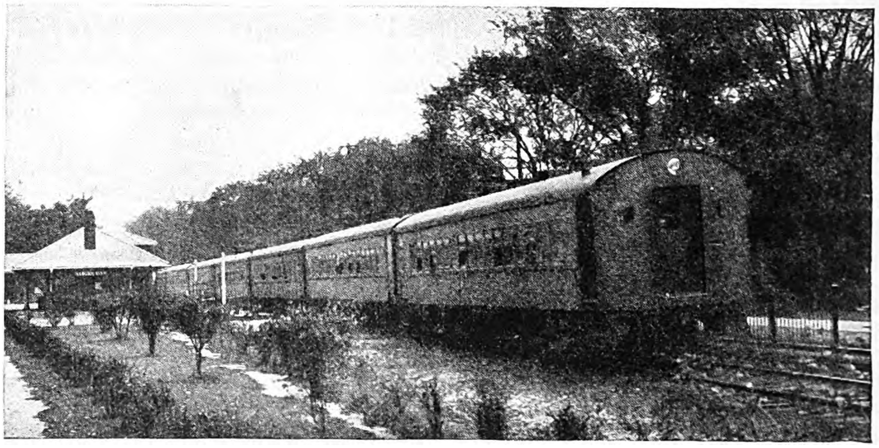
In spite of increase in the demands upon our transportation system, there has been practically no increase in the



A 6000-ton coal train on a 2 percent up grade of the Virginian Railroad, hauled by three 215-ton, 11,000 volt, single phase, Westinghouse-equipped power units number of freight-train-miles or in the number of locomotives for the past 20 years. This means that our train units are becoming progressively heavier, and trains are being moved at higher speeds. The increase in ton-miles per hour has been nearly 50 percent in less than 10 years. The size of the locomotive has likewise grown, and the trend is conclusively toward more and more horsepower per train.

A crack silk train of the Chicago, Milwaukee, and St. Paul drawn by a 300-ton, 3000-volt direct current, Baldwin-Westinghouse electric passenger locomotive

Rail traffic, like automobile traffic, seeks those highways which are most advantageously situated. Half of our route miles carry about 90 percent of our traffic; while the great trunk lines, which constitute only about 10 percent of our route mileage, handle at least half the traffic. There is, therefore, an increasing pressure of traffic on these major routes which has been met by increasing the size and speed of the trains.



Multiple unit operation in heavy duty suburban passenger service on the Long Island Railroad. This is a familiar type of car in many metropolitan localities

So far, the steam locomotive, which has recently undergone conspicuous and notable development, has kept pace with our needs and will continue for many years to be the mainstay for most railroad mileage; but there may be serious question if it can meet the demands of intensive trunk-line operation after the next 20 or 30 years. Double and even treble the present movement may conceivably be the requirement.

With electric operation, on the other hand, the amount of power that can be applied to each train is practically unrestricted, and electric trains of any size can be operated at any speed within the limits set by the road-bed, draw-bars, and other mechanical equipment. Hence, an electrified railroad has greater capacity than the same road under steam power. To electrify a rail highway is to broaden it.

Behind the great electrification undertaking of the Pennsylvania Railroad, therefore, may be seen a recognition of our future transportation needs, a vision of an unhampered and ever-expanding flow of traffic, and the desire to give the public the utmost in railroad service.

Important also is the inauguration by the Reading Railroad of the electrification of its lines radiating from Philadelphia; and it is understood that ultimate extensions will be made for high speed and through service. Increasing interest is also being manifested by other railroads in electrifying sections of their main lines.

Parallel to the progress in developing the utility of railroad electrification, has gone on an evolution in the kind of electric power employed. All the early systems followed street railway practice and used direct current at 500 volts supplied by a third rail. In 1902, B. G. Lamme, Chief Engineer of the Westinghouse Company, announced the results of his experimental development, sponsored by George Westinghouse, of an alternating-current motor which could operate at all the various speeds and under the different conditions required by railway service. This announcement, which indicated the possibility of serving any track with a single working conductor at any desired voltage and of supplying power to trains in any desired amount, instantaneously and effectively, aroused world-wide interest.

In 1905, the New York, New Haven & Hartford, being governed by plans for future extension, adopted the new alternating-current system with overhead conductor at 11,000 volts. This method of operation has since been adopted and made standard by Norway, Sweden, Germany, Austria, and Switzerland, and, in this country, by the Grand Trunk St. Clair tunnel installation, the Hoosac Tunnel of the Boston & Maine, the Great Northern, Pennsylvania, Norfolk & Western, and the Virginian Railroad.

The success of the high-voltage overhead system of the New Haven stimulated the development of high-voltage direct-current equipment, and this current has been applied for various lines at 1200, 1500, 2400, and 3000 volts. Shortly after the war, the French Commission decided upon 1500 volts, direct current, as the official standard for France. The same system is in use in Japan, Java, Holland, and some other countries, while 3000 volts direct current is in use in South Africa, Chile, and Brazil, and by the Chicago, Milwaukee & St. Paul in this country.

The most extensive electrifications now being carried out in this country are with single-phase alternating current, as this system has greater promise for future advantage than any other.

ANOTHER PEKING SKULL DISCOVERED[1]

By PROFESSOR G. ELLIOT SMITH, F. R. S.

AT a meeting of the Geological Society of China in the last week of July, Prof. Davidson Black announced the discovery of another skull of Peking man.

In *Nature* of March 22, 1930[2], an account was given of the discovery of a series of remains of *Sinanthropus*, culminating in the recovery of an almost complete braincase by Mr. W. C. Pei on December 2, 1929, while clearing a sheltered recess of the main deposit at Chou Kou Tien. Some days before this skull was found, five human teeth were recovered from a spot higher up in the shaft, where they were associated with the skull of a large deer and some pieces of fossilised bone and blocks of stone, which were brought to the laboratory in Peking for examination.

This material was "developed" during the third week in June by the technical assistants working under Professor Davidson Black's supervision, and he found that there were enough fragments, which fitted together, to form the greater part of another uncrushed skull of *Sinanthropus*. He waited until the return to Peking of Dr. Wong (Wong Wen Hao), the Director of the Survey, before making the public announcement of his important discovery.

FOR reasons which are not yet clear to those who have not seen the actual specimens, Professor Davidson Black regards the skull found on December 2, 1929, as that of a young woman, and the calvaria, the discovery of which is now reported, is in his opinion that of a young adult male. It conforms to the same general type as the skull previously found, and its proportions are similar. But the braincase is not so thick and the frontal eminences not so pronounced. The most interesting new fact revealed in this discovery is the nature of the root of the nose, which is broad and flat, quite unlike that of Piltdown man.

The newly discovered skull was found in association with a number of teeth which can be assumed to have belonged to the same individual. This fact adds to the interest of two mandibles found in 1928 in association with the crushed parts of the respective braincases.

The remains of four skulls of *Sinanthropus* and teeth of at least six other individuals have so far been found. Thus there is available for study in China a much richer material of early Pleistocene man than the fragments of the individual specimens of *Pithecanthropus* and *Eoanthropus* provide. Moreover, the geological age of the Chinese fossils can be established with more certainty than that of the other two primitive genera, which are assumed to be roughly contemporaneous.

The fossils from Java and Sussex were found in gravels, where they had been deposited by running water. Although there is little doubt which of the heterogeneous fossils found in these gravels were contemporaneous with the human remains, in the case of the men of Peking, who left their bones in the cave where they lived, there is less room for doubt that the bones of animals deposited alongside them provide more certain data for the estimation of their geological age. Thus the claim made by Père Teilhard de Chardin and Dr. C. C. Young that *Sinanthropus* lived in Lower Pleistocene times rests upon a surer foundation than the similar claims that have been made in the cases of *Pithecanthropus* and *Eoanthropus*.

Further, the conditions under which the discoveries are being made at Chou Kou Tien hold out a greater promise of further evidence than in the cases where the fossils have been scattered by running water. Thus a series of fragments have already been recovered every autumn since the type tooth was recovered in 1927, and it is not unreasonable to expect that much more still remains to be found in this cave, and possibly in other fossil beds in the neighborhood. So far no worked tools have been found in the cave; but if such should be recovered, their association with the human remains will be less uncertain than in the case of the other Pleistocene men's implements.

FOR these reasons, in addition to the intrinsic interest and morphological significance of the skulls of *Sinanthropus*, the discoveries in China have an importance which is unique. It is a matter for congratulation that the investigation of this site should have fallen into such competent hands and that ample facilities and skilled assistance should be available for the work, which is being conducted with great thoroughness and insight.

HOW PLUTO'S ORBIT WAS FIGURED OUT

By HENRY NORRIS RUSSELL, Ph. D.

Chairman of the Department of Astronomy and Director of the Observatory at Princeton University
Research Associate of the Mount Wilson Observatory of the Carnegie Institution of Washington

NOW that the new planet has been detected upon photographs taken years ago we can be sure that we have a good idea of its orbit. But doubtless many people still are wondering why it took so long to be sure in what sort of path it was moving.

How astronomers can work out the orbit of a planet which they have been observing but a few weeks is a mystery to most people. Indeed we might go further, for even the graduate student of the science, who has gone through the long chapter of mathematical formulae to be found in treatises on the calculation of orbits and the still longer computations which actually apply them, has often no very clear idea of the *rationale* of the complicated process. He can not see the woods for the trees.

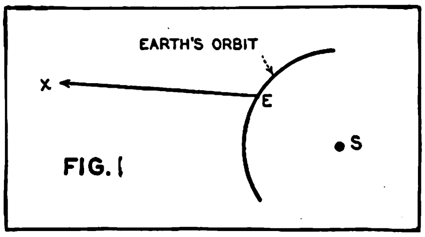

FIG. 1

Yet the thing is not really so hard to understand and, with due apologies to the reader whose tastes do not run along mathematical lines, let us for once consider the reader whose interests do, and try to explain as simply as possible how the apparently impossible thing is done.

FIRST of all we must realize what our planetary observations actually tell us. They give the apparent place of the body in the heavens among the stars; that is, each observation tells us very precisely in just what *direction* the planet lay from the earth (more precisely, from the particular spot on our planet where the observation was made) at an exactly specified moment. But an observation by itself tells us nothing at all about the planet's *distance*. Since the earth's motion about the sun can be accurately calculated we know just where it was at the time of observation (say at E in Figure 1). We can lay off this point on a diagram and also draw in the line EX which runs in the direction in which the planet was seen. (This line would usually run a little above or below the plane of the rest of the picture, but we may leave such details to the actual computer.)

But *where* is the planet upon this line? This is the main problem and it would be very difficult to solve if we did not know the laws according to which the planets move. Suppose that we have two observations, made at the time when the earth was at E_1 and E_2 (Figure 2). If the planet was standing still in space we could locate it at the intersection Y of the lines E_1X_1 and E_2X_2 on which it lay at these moments. But it was actually moving, and so can not have been at Y, wherever else it was.

NOW—to take a simple case first—suppose that the planet's orbit is a circle. We may then make any guess we please about its distance (say SR in Figure 2), draw a circle with this radius and find two points P_1 and P_2 at which the planet must have been if our guess was right. But *was* it right? We can test this by using Kepler's Third Law—that the squares of the periods of the planets are proportional to the cubes of their distances from the sun. We can find by measurement on our diagram, or far more accurately by calculation, what fraction the arc P_1P_2 is of the whole circumference. We know the time taken between these points and so can calculate what would be required to complete the whole orbit at this rate. If the result agrees with Kepler's law our guess was right. If not it was wrong and we try again with a new assumed distance SR′ and get two new positions P'_1 and P'_2. This time perhaps we find a motion slower than Kepler's law allows, whereas the first time it was too fast. The true value then lies between our two guesses and a few more tries will lead us step by step to the correct result.

Such calculations are often made in the case of a newly discovered asteroid to get a rough idea of its orbit and predict where it may be found a month or so later. Most of the characteristics of the general problem are well illustrated by this simple case. In the first place we see how the application of the law of motion turns an apparently hopeless problem into a very simple one. Secondly, we may note that a very small error in our observations may cause a serious one in our results. Suppose that we have got the direction of one of the lines, say E_2X_2, a little wrong. The distance P_1P_2 will then be wrong and, when we compute the time required to make the circuit of the whole orbit from that of this short arc, our error will be greatly magnified; and the same will be true of the final calculated distance. For this reason the computer must assure himself at the start that the observations which he uses have been made with skill and care before he wastes time on useless calculations.

AGAIN we may notice that our problem, as illustrated in Figure 2, admits of two solutions. Instead of starting with an assumed distance less than SY we might have adopted a greater one (SR″ in the figure). We would then have found the planet moving backward about the sun, but by the same process of trial and error we could have hit on an assumed distance at which the rate of motion would agree with Kepler's law. Two quite different planets, then, one relatively near the sun and moving forward, the other farther away and moving backward, each in a circular orbit, might both have been exactly on the observed lines at the correct dates. Later on, of course, their directions from the earth would differ and a third observation would tell which was the true answer (practically, since all of the thousand and more known planets move forward, no doubt would arise).

When the orbit is an ellipse (or a parabola or a hyperbola in the case of a comet) the problem of calculating it is much more complicated but the principles which have just been illustrated still hold good.

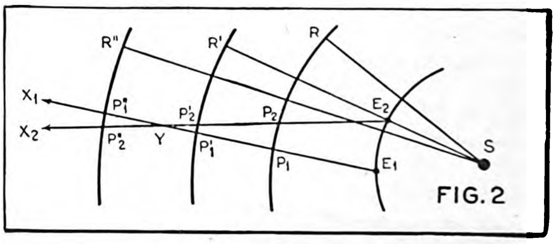

FIG. 2

In this case we must have three observations instead of two—which can be seen from very general considerations. If we have to find the values of a certain number of unknown quantities

—say six—we must have an equal number of equations (or, more generally, of known relations) from which to find them. No algebraical skill can get out the values of all six from only five independent data.

Now each observation of a planet gives us two such independent data, the right ascension and declination. To specify completely a circular orbit we require four "elements"—the node and inclination of the orbit plane, the planet's distance from the sun, and its position on the orbit at a given instant. Two complete observations giving four data to work on should therefore just suffice to work out a circular orbit; as they do. For an elliptic orbit there are two more elements to be found—the eccentricity and the longitude of perihelion, making six in all; and three observations will give us just what we need for a solution.

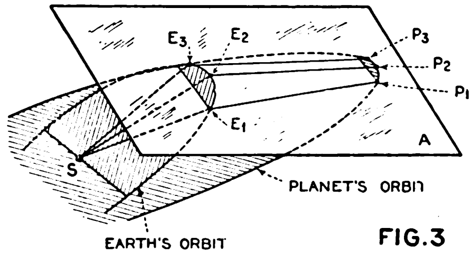

FIG. 3

Once again the principal problem is to find the planet's distance. How it is done may best be explained by going back directly to the law of gravitation. We have now to take account of the fact that the orbits of the earth and the planet are in different planes both passing through the sun, as shown in Figure 3. $E_1E_2E_3$ and $P_1P_2P_3$ are the positions of the earth and planet at the three dates of observation. It is always possible to pass a plane A (the least shaded one in the figure) through the line E_1P_1 in such a way that E_3P_3 is parallel to it (though in the case represented lying higher) and E_3 and P_3 are at equal heights above the plane. Now the sun attracts both the earth and the planet, so that their orbits are curved and E_2 and P_2 lie higher than the other two points on each orbit. But since the earth is nearer the sun than the planet, the sun attracts it more strongly and curves its orbit more, so that E_2 will be farther from the one line than P_2 is from the other, and will be higher above the plane A than P_2 (the more so because the earth's orbit is more highly inclined to A than is the planet's). Hence the line E_2P_2 will not be parallel to A, but will slope downward and meet it at some point beyond P_2.

The angle of this slope may be found from our observations, which tell us just where the three lines are—though not where the points P lie on them.

Now, making any convenient assumption about the distance E_2P_2, it is possible to calculate the influence of the sun's gravitation in curving the planet's orbit (that on the earth's is of course known) and hence to find what the slope of this line should be. Successive trials would then lead us to the correct value. When, as in practice, the arcs E_1E_3 and P_1P_3 are but small parts of the orbit it is possible to set up an algebraic equation which saves the time-consuming process of solution by trial and error and gives the desired distance directly. This equation is of the eighth degree but its solution has been made much easier by the calculation of special tables and presents no great trouble. When once the planet's distance at the time of one observation has been determined, its distances at the other two dates may be found by another equally simple application of the laws of motion under gravity (which, however, we have not space to describe in detail). To calculate the orbit about the sun is then easy enough. It may be noticed that, though the planet's orbit is drawn as an ellipse in the figure, the same reasoning would apply in the case of a hyperbolic comet. In fact the solution leads automatically to a determination of eccentricity of the orbit and the size and shape, whatever they may be.

Once again a small error in any of the observations is likely to be greatly multiplied in the results of the calculation. A "first orbit" based on all three observations is therefore usually of low accuracy. It serves completely, however, for predictions good enough to keep track of the planet until, some months after the discovery, it is lost to observation in the vicinity of the sun. Then by utilizing the data obtained in this interval a better orbit can be calculated, sufficient for finding the planet next year, and sometimes, as has recently been illustrated, on old photographs; and then a still better orbit may be calculated.

The general equation for finding the planet's distance has sometimes one real solution and sometimes three, leading to three different orbits in any of which a planet could move so as to be on the three given lines at the given instants. Charlier the distinguished Swedish astronomer has, however, shown that when a body is observed near opposition there can only be one solution of the problem and this is practically always the case for planetary discoveries. For a comet observed near the sun there may be three solutions, as happened for the great daylight comets of 1843, 1882, and 1910.

For a distant body like the new planet Pluto the apparent motion is slow and the effects of even very small observational errors may be considerable until observations covering several months are available. The delay in calculations and publishing an orbit of this most interesting body is therefore good evidence of the full comprehension which its discoverers had of the problem, as well as their excellent judgment.—

Cortina d' Ampezzo, Italy.

◆

Editor's Note: In the light of Professor Russell's lucid explanation of the standard method by which astronomers work out a new orbit, some notes on Pluto's orbit, by the astronomers Ernest Clare Bower and Fred L. Whipple of Lick Observatory, published in the August number of the *Publications of the Astronomical Society of the Pacific*, make interesting reading. These astronomers state that, between last January and June, more than 100 accurate observations of the orbital arc described by Pluto were made available by various astronomers, "but," they add, "these alone would not suffice were they not augmented by observations made possible by the identification of the object on plates taken before its discovery." This was because the January-June, 1930, observations would cover only about 1/500 of the full orbit—a pretty short arc from which to work out an accurate orbit. But at this juncture Mount Wilson, Yerkes and one other observatory came to the rescue with some old plates of the vintage of 1919, 1921 and 1927, which they had found in storage. With these "pre-discovery" observations the new arc now represented a span of 11 years or about 1/25 of the whole circumference of the orbit, a respectable base line from which to perform calculations. How closely Pluto now has been pinned down is shown by the fair agreement in the following results of various astronomers' calculations:

	By Bower and Whipple	By Nicholson and Mayall
Perihelion passage due	Feb. 27.473, 1989	June 5.5, 1988
Eccentricity of the orbit	0.253741	0.2575
Inclination of the orbit	17°8′57″	17° 09′
Period of revolution	249.1661 years	251.80 years

TELEVISION NEEDS NEW IDEAS— AND LESS BALLYHOO

The author

By A. DINSDALE, Assoc. I. R. E.

EVER since I reached the hospitable shores of the United States, nearly every person I have met has asked me: "Well, how long do *you* think it will be before we get television?" I never have felt any particular urge to assume the rôle of prophet, and it seems to me that prophesying about television is about as thankless a job as that possessed by the weather forecaster.

To begin with, it depends largely upon what you mean by television and what you expect it to do. In Europe the public, educated by a vast amount of advance publicity designed to boost somebody's over-enthusiastic claims, has acquired definite and rather high standards about television. It has heard so much about being able to "see the world from your own fireside," to watch the finish of the Derby or the final of the Cup Tie (England's star football match), that it expects just that. And as nobody so far is able to provide the necessary apparatus and service, the public has become somewhat apathetic. It has metaphorically rolled over and gone off to sleep again until something startling happens to wake it up. Extensive lecture tours have shown me that there is no lack of interest on the part of the British public, but much disappointment at the non-fulfilment of promises. "Hope deferred maketh the heart sick."

IN America the position seems to be rather more complicated. In the first place, there seems to have been even more ballyhoo about television over here than there has been in Europe. There are more people working on it, some earnestly and scientifically, and some not so scientifically, some with laudable aims, and some with aims not so laudable.

Since I arrived here I have talked with most of the leading workers in the field, and I can find no unanimity as to what television must be able to do. Dr. Alexanderson, for instance, thinks that a limited form of television will be sufficient, while Dr. Ives looks to the time when television will be able to do all that the talking movie can do, and as well. He contends, however, and I think quite rightly, that the system of television as developed by the Bell Telephone Laboratories for use in conjunction with the telephone, is quite adequate for the purpose. But that is a specialized application. The public expects broadcast television.

With television workers themselves at variance as to what television must be able to do, it is not surprising that the general public has no definite notions on the subject. At least, nobody seems to be able to tell exactly what the public wants or expects. Under these circumstances, the obvious thing to do would appear to be to give the public what you have, try to educate them into liking it, and keep on improving on it.

THAT television today is up against an impasse is a fact acknowledged by most authorities, although sporadic articles in the daily press would lead the layman to believe that television is soon to be ready for general use. This impression is fostered by interesting experiments on a laboratory scale which have been heralded as forerunners of practical home televisors. But even the best television equipment available today falls far short of the desired home radio-movie goal, and it becomes increasingly apparent that new paths must be beaten before present-day mechanical and electrical difficulties are overcome. The author of the accompanying article, formerly editor of *Television* (London), presents a point of view that is refreshing after the deluge of misleading publicity of the past few years.—*The Editor.*

The general public, however, will have none of the present limited form of television, which can show only a head-and-shoulder view of some distant speaker or singer, and that imperfectly. The fans, who love tinkering with something, have taken to it, of course, both here and in Europe, but commercial sets just cannot be sold. In England, the Baird Company's attempt to sell machines has met with but scant success. They blame the limited broadcast facilities granted them by the B.B.C.: 11 to 11:30 A.M. five days a week, and midnight to 12:30 A.M. two nights a week. But over here, where broadcast facilities are available on a more liberal scale, I am told that attempts to sell inadequate televisors are meeting with no better success.

The real reason for this failure is not far to seek, and is very simple. There is definitely no entertainment value in the present head-and-shoulder images. Realizing that fact, the Germans have made no attempt as yet to sell televisors; they are devoting all their energies to further experimenting.

THERE are some who disagree with me about the entertainment value of the present image, and point to the fact that something like 75 percent of a talking film is composed of close-ups. True, but the film shows more of the individual, more than one person at a time, has a lot more detail, and the producers have had years of experience with their medium of entertainment and have learned how to make it entertain. On the latter score the television people have reached the point where they say that "a new technique will have to be developed." Nobody knows yet just what form that technique will take. And at this stage they can not be expected to know.

Others who disagree with me contend that a start must be made somewhere, sometime, and point to the crudeness of the art of radio-telephony when sound broadcasting first started. It is difficult to compare two things which are totally different, but I believe that sound broadcasting, when it started, had more power to interest, entertain, and attract than has the art of television at the present time.

Just what the public expects of television is a question nobody can answer. Some go so far as to express doubt as to whether the public wants television at all! I think there can be no doubt that, after what it has been led to expect of television, any serious attempt to stampede the public into patronizing the present limited form of television will not only meet with failure, but will do the youthful art irreparable harm. Some harm has already been done.

Let us, therefore, survey the present state of the art from a technical angle. Let us create a standard of performance and see if present methods will permit of its achievement.

But let me make one thing clear before I proceed further. In reading over what I have written it would appear that I am a thorough pessimist, more of an enemy than a friend to television. Far from it. There is no doubt at all in my mind that television will ultimately arrive. It will eventually be able to do all that has been promised. Televisors will one day be as common in our homes as radio sets are today, and a television industry will grow to the proportions of the present radio industry.

But before all these things can happen we shall have to think up a few new ideas.

It is an extraordinary fact that television has not, so far, developed any brand new ideas for its own exclusive use. All its ideas and apparatus are either borrowed from some other field of scientific endeavor, or they have been in existence, but not made use of, for many years.

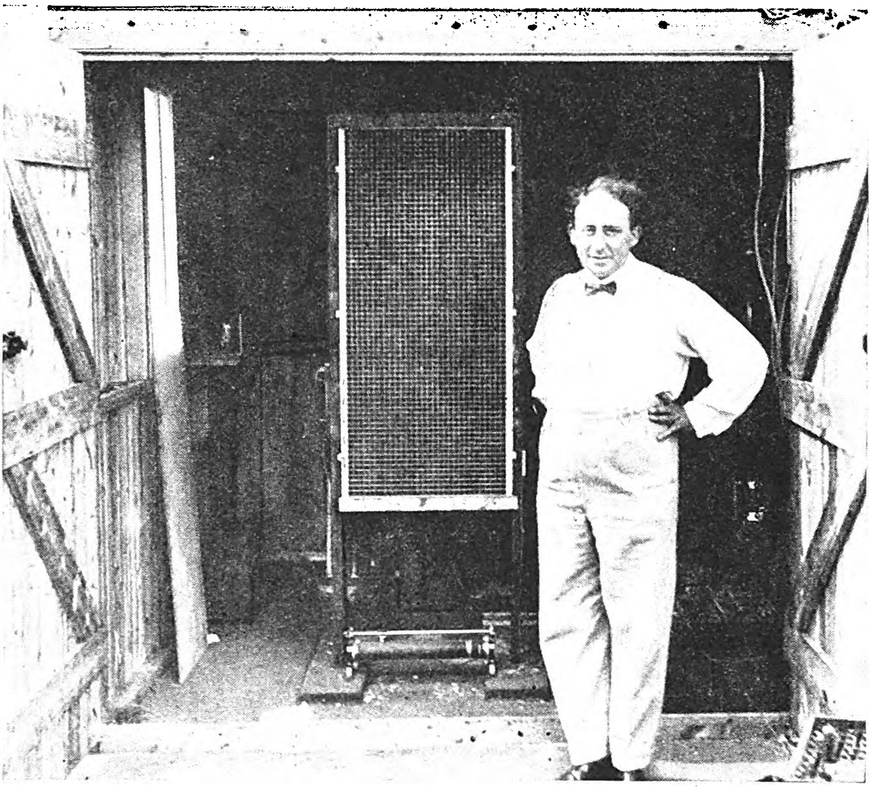
Take the scanning disk, for example. Invented by Nipkow in 1884, it lay idle until it was coupled with such modern inventions (taken from other fields) as the neon lamp, thermionic tube, and photo-electric cell, when television was produced. Nipkow could have done it in 1884 if he had had the use of these modern facilities.

THE large viewing screens of Jenkins, the Bell Telephone Laboratories, and Baird are reminiscent of the walls of selenium cells controlling distant electric bulbs, which were suggested by several early enthusiasts and actually constructed by Rignoux and Fournier in 1906.

The use of cathode-ray tubes was first suggested by Campbell Swinton in 1911, and they were experimented with soon after by Boris Rosing in Russia and Belin in France.

All these things have, of course, been vastly improved upon and made to perform incredibly well, thanks to modern facilities, but they have their limitations. What astonishes one is that all the present-known workers, knowing these limitations, are content to pursue the old methods. Some entirely new principle is needed, and needed badly. And it is quite on the cards that the present workers will get so stale and hide-bound that the new idea, when it does come along, will pop out suddenly and unexpectedly from a source never previously heard of.

Before we can proceed to an examination of the limitations of present television apparatus and methods, it is necessary to set forth some standard of achievement which must ultimately be met, and see how far toward that standard we can go with the means at present available.



Baird's large television receiving screen. The extreme complexity of devices of this nature is an important indication of the need for new ideas in the art

My guess is that television, for home entertainment purposes, will have to be capable of embracing a field of view, either indoors or outdoors, as extensive, complete, and flexible as is at present coverable by means of a motion picture camera, and the detail presented will have to be comparable with that of the motion picture also. After all, as an entertainment medium, television must go into direct competition with the motion picture, or couple up with it so that films can be distributed and simultaneously exhibited all over the country by television methods. It will displace the film for spot news, although the film will always be wanted for record purposes.

The home screen upon which the television images are depicted will have to be, for comfort and convenience, not smaller than nine by twelve inches, unmagnified. The magnifying lenses at present in use are undesirable for several reasons. Many of them are so badly designed and arranged that they distort the edges of the picture. Even if well arranged, they magnify all the defects in the image, cause loss of light, and, perhaps most important, limit the number of observers to two or three, and force even that number to locate themselves, often in discomfort, directly in front of the lens. The standard of comfort of the home movies must prevail on this point.

Having thus set the standards of field of view and size of screen, the next important step is to fix quantitatively the amount of detail which must be provided. Here it is necessary to guess a bit again. If scanning is to continue to be carried out in parallel strips or lines, my guess is that we shall have to provide 100 lines per inch. That means that, for a nine by twelve inch receiving screen, unmagnified, we shall have to resolve the image into $900 \times 1200 = 1,080,000$ picture elements. If we set the transmission speed at 15 images per second—a rather low figure—the frequency of the A. C. picture impulses which we must transmit, either by wire or by wireless, works out at

$$\frac{1,080,000 \times 15}{2} = 8,100,000 \text{ cycles,}$$

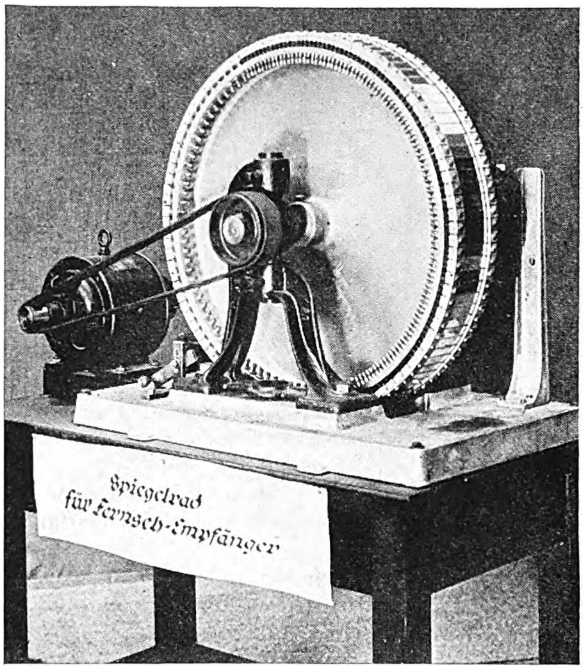
or 8100 kilocycles.

WE are now faced with two major problems: (1) terminal equipment capable of fulfilling the above requirements, and (2) channels of communication which will successfully transmit frequencies up to 8100 kilocycles.

Let us consider terminal equipment first. Remembering that the circumferential distance between the holes of a scanning disk must be equivalent to the long side of the picture, in this case twelve inches, and that there must be 900 of them, we should require a scanning disk nearly 300 feet in diameter to fulfill the requirements set out above! And if we used a flat plate neon tube, we should need one with a plate measuring slightly in excess of nine by twelve inches, and such a tube would require a prohibitive amount of amplifier power to illuminate it. The whole conception is preposterous and ridiculous.

The Jenkins drum scanner provides no solution to the problem; it also would assume unwieldy proportions. There remains the Weiller mirror drum, which would require 900 mirrors, and if these were only one inch wide the diameter of the drum would be something like 25 feet.

That exhausts all known mechanical methods of scanning which have proved at all successful. It is obvious, therefore, that we must either relax our requirements for television or seek other and non-mechanical methods.



The Weiller mirror wheel used in television scanning. For large images, this device becomes unsatisfactory

BEFORE the days of the thermionic tube, we achieved, or attempted to achieve, radio-telegraph communication by just such cumbersome "brute force" methods. Now we have thrown all our unwieldy machinery into the discard, and achieve our object a thousand times better by harnessing electrons. We shall have to discover some method of harnessing electrons to do our bidding in the television field. A stream of electrons travels with the speed of light, it is weightless and therefore inertialess, and it can be controlled electrostatically or magnetically.

The fundamental essence of the television problem may be defined as the time element, or, if you like, speed; so much has to be done in such a limited space of time. As we have already seen, 16,200,000 picture elements have to be dealt with *per second.* Obviously, only electrons are capable of handling such a gigantic number within the time allowed.

The only electron device at present known which seems to offer a ready solution to the problem is the cathode-ray tube. It has been experimented with for many years, and several workers are still busy on it, trying to adapt it for both transmission and reception purposes. As at present made and used, the cathode-ray tube has many disadvantages. It is expensive, both as to first cost and as to auxiliary equipment and operation, its life is short, and there are still difficulties in the way of adequately controlling the scanning movements of the electron stream. It remains to be seen, therefore, whether the cathode-ray tube is the best practical embodiment of the purely electronic method of achieving television.

So much for terminal equipment.

Coming now to channels of communication, one is almost tempted to say that it will never be possible to transmit 8100 kilocycles over either a wire or a radio circuit. But in scientific matters today's impossibility is tomorrow's commonplace achievement. At present it might be possible to transmit such an enormous frequency by radio, but only on wavelengths below ten meters. Obviously we shall have to discover some new technique or principle in radio communication also. That it is already long overdue is evidenced by the fact that the entire spectrum of wavelengths used for all radio communication purposes is already full to overflowing; radio communication cannot develop any further until it is released from its strait-jacket. Personally, I think the new principle discovered by Dr. J. Robinson of England, and incorporated in the Stenode Radiostat receiver, will not only solve the overcrowding problem but also make it possible to transmit the enormously high frequencies required for television.

That is my conception of the problem of television as it stands today. A gloomy picture, you may say. Or again you may ask me: "How long will it be—?" As I said at the outset, I am not going to be inveigled into prophesying, but I feel very optimistic about the future development of television. It is clear that much remains to be done, and it is equally clear that television is going to provide yet another example of the survival of the fittest. So much remains to be done that only those who are backed by almost unlimited resources in the shape of money, brains, and laboratory facilities stand any chance of winning through and reaping their reward.

The work which has been done to date, and about which there has been so much ballyhoo, must be regarded in the light of a preliminary canter over the course. Already there is evidence that the most serious contenders in the race for television are abandoning present methods and working quietly behind locked doors on something different. In Germany, Dr. Karolus, working in conjunction with the Telefunken Company, has been silent, but not inactive, for a year.

IN this country, the television staffs of the General Electric and Westinghouse companies have just been concentrated in the R. C. A.-Victor plant at Camden, New Jersey. That the R. C. A. group really means business is evidenced by the utterances of its executives, and if further evidence is required of the imminence of television on a really commercial and entertaining scale, there is the projected 250,000,000-dollar Rockefeller radio city which Merlin Hall Aylesworth, President of the National Broadcasting Company, says is to be built around television. It is estimated that this building will be ready in three years, and that is as near as I will go to prophesying when television will be ready to make its bow to the public, not in so perfect a form as I have outlined as being ultimately necessary, but at least some way towards it.

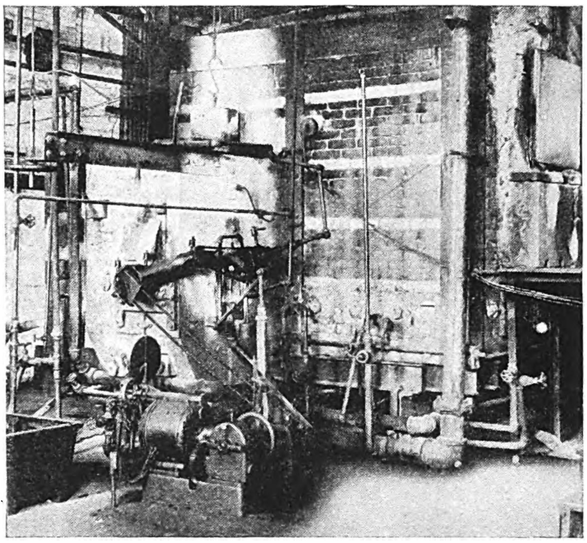
And finally, I have been asked who will win the race, Europe or America. Well, one of the essential qualifications of the competitors, mentioned above, has to do with financial resources, and America has more money to spend on television than has Europe, and America seems to be more determined. So with that I will leave the American workers to it, and wish them the best of luck.

●

Editor's Note. Although we are in hearty accord with Mr. Dinsdale in the general tenor of the foregoing article, we can not help but take exception to the statement ending at the top of this column. There are thousands of amateurs in this country who are learning the fundamentals of television by experimenting with their own equipment. And it is well known that the radio amateur is never content to follow the beaten paths. His record in the development of the short waves justifies this statement, and we do not feel that we are too optimistic when we express the opinion that the ranks of amateur radio will contribute some of the new ideas needed for the development of television.

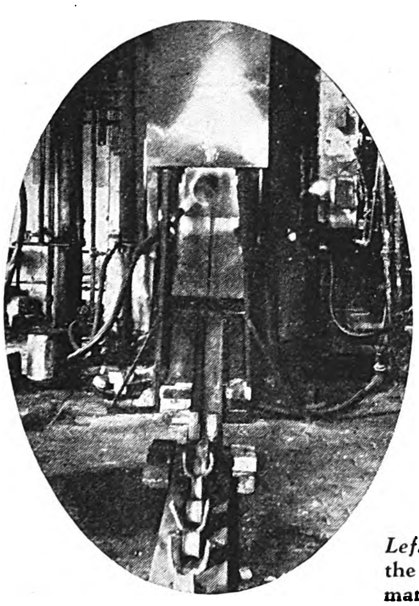
GLASS TUBING BY THE MILE

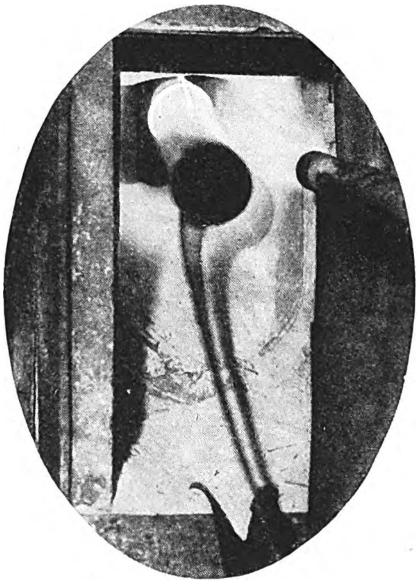
THE old method of making glass tubing by blowing, while the hollow cylinder was pulled out and cooled, was an exceedingly crude process and the variations in the size of the bore were great. Now, however, by the aid of cleverly designed machinery, although under the principles of the archaic methods, glass tubing is made by the mile. The machines operate continuously, drawing the molten glass from the furnace, cooling it at a distant point and cutting it off in pre-determined lengths, automatically, by a special mechanical device. In this method, as in the hand process, there is a long line of easily broken tubing in constant motion between the blow-pipe and the far end where the cutting operation takes place.



View of the rear of the glass melting furnace

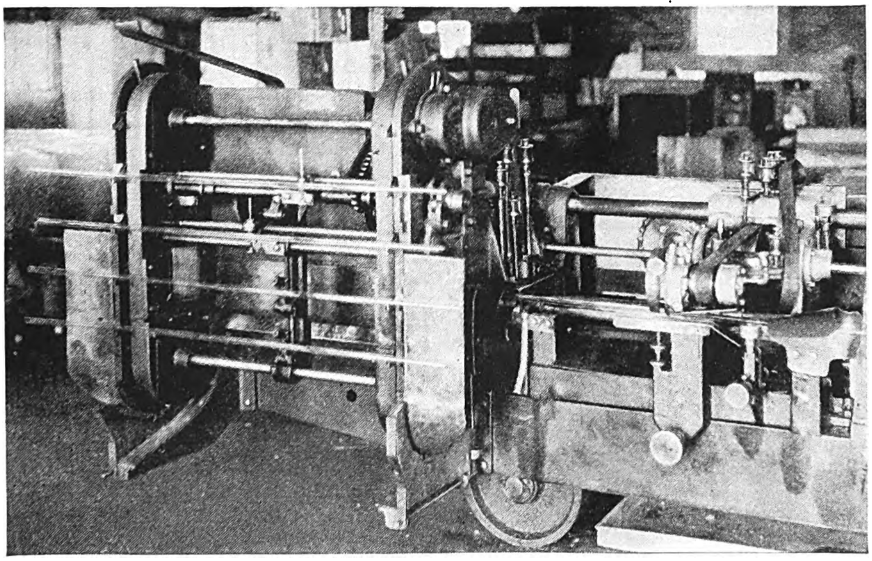
A tank furnace supplies a steady stream of molten glass. As the viscous glass flows to the aperture, it is kept very hot by the glass blow-pipes. The glass forms a tube over a hollow mandrel by the aid of air which is forced through it. The air pressure is slight, being only one or two ounces per square inch. If this air should be cut off, a cylinder of solid glass would form. After the tube is formed comes the drawing process which is dependent on a machine which pulls away, continuously, the rapidly cooling tubes of glass. Two endless chains serve to carry pressure plates which grip the tube without fracturing it. The motion is positive and in one direction. The cooled tube is drawn away from the furnace, dragging away more of the molten glass which is to form the tube over the hollow mandrel which purveys the air for blowing. The machine is dealing with a very peculiar substance and the slightest tendency to buckle up would fracture the tubing. The speed of the pulling chains may be adjusted at will.





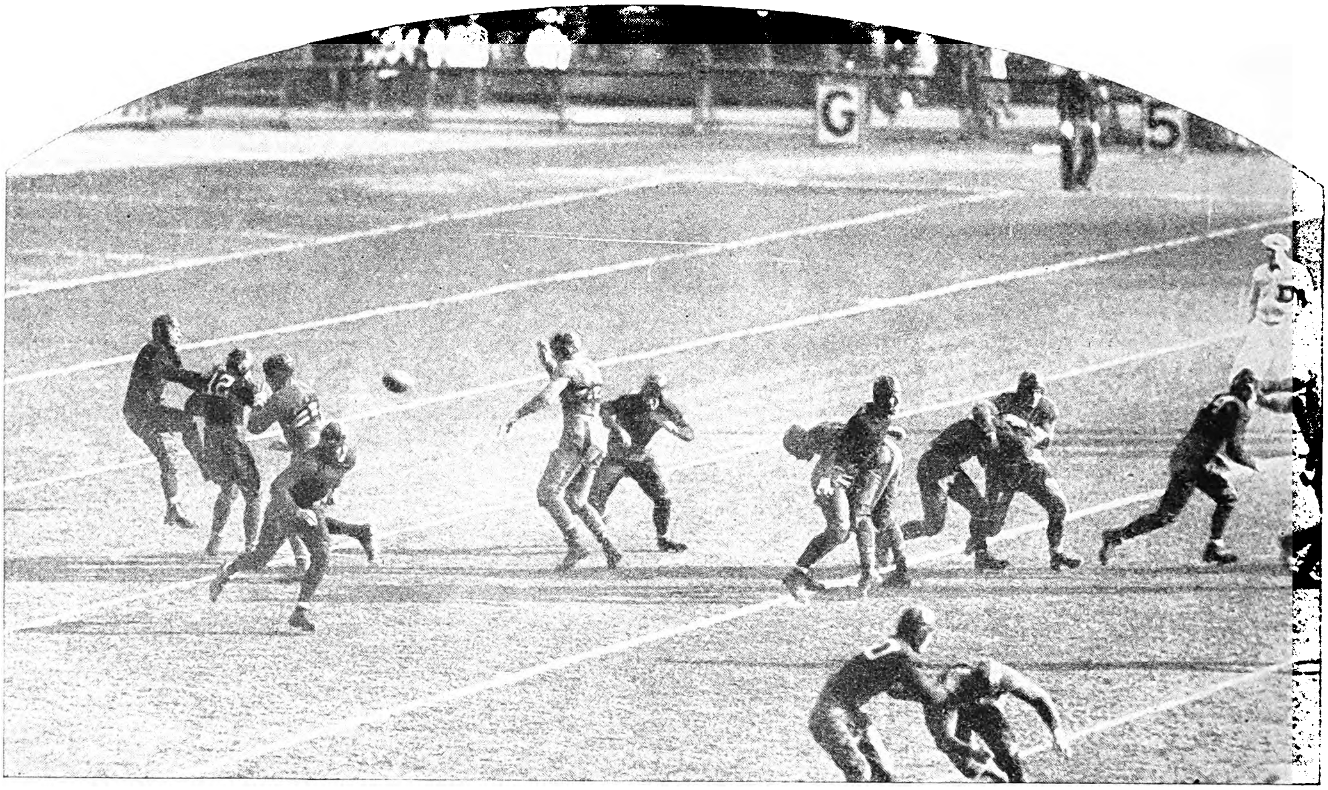
Left: Discharge end of blow pipe from which the glass is drawn. *Right:* Heater muffle and mandrel forming the continuous glass tube

The pulling machine is supplemented by a device for breaking off the tube in pre-determined lengths as it is pulled along. After the tube leaves the endless chains it encounters a second set of guide-rolls mounted on vertical spindles. Next it passes over a pressure table which yields vertically. Then it enters a part of a special wheel and is broken off to the proper length. This length is finally delivered from the machine for inspection and packing. The cutter wheel co-acts with the pressure table. That is to say, the cutter wheel moves downward and comes into contact with the work at the beginning of its own stroke. The cutter wheel cuts a surface groove on the glass. It is not designed to effect a complete severance of the glass but to make a point of weakness. A second wheel revolves intermittently and exerts a transverse pressure against the work at a point in advance of the cut, thus breaking it off at the groove. The demands for uniform glass tubing, in science and industry, are many.



After the glass tube has been drawn from the furnace with the aid of a "pulling" machine, it is cut off with this machine and the broken-off length is delivered

We are indebted to the Libbey Glass Manufacturing Company of Toledo, Ohio, for permission to inspect the interesting process.



The Army blocks a Notre Dame punt in their famous 1929 game

HOW MANY MINUTES OF PLAY IN THE AVERAGE FOOTBALL GAME?

By **HUGO L. RUSCH**
Supervisor Technical Data Section, Johns-Mansville Corp.

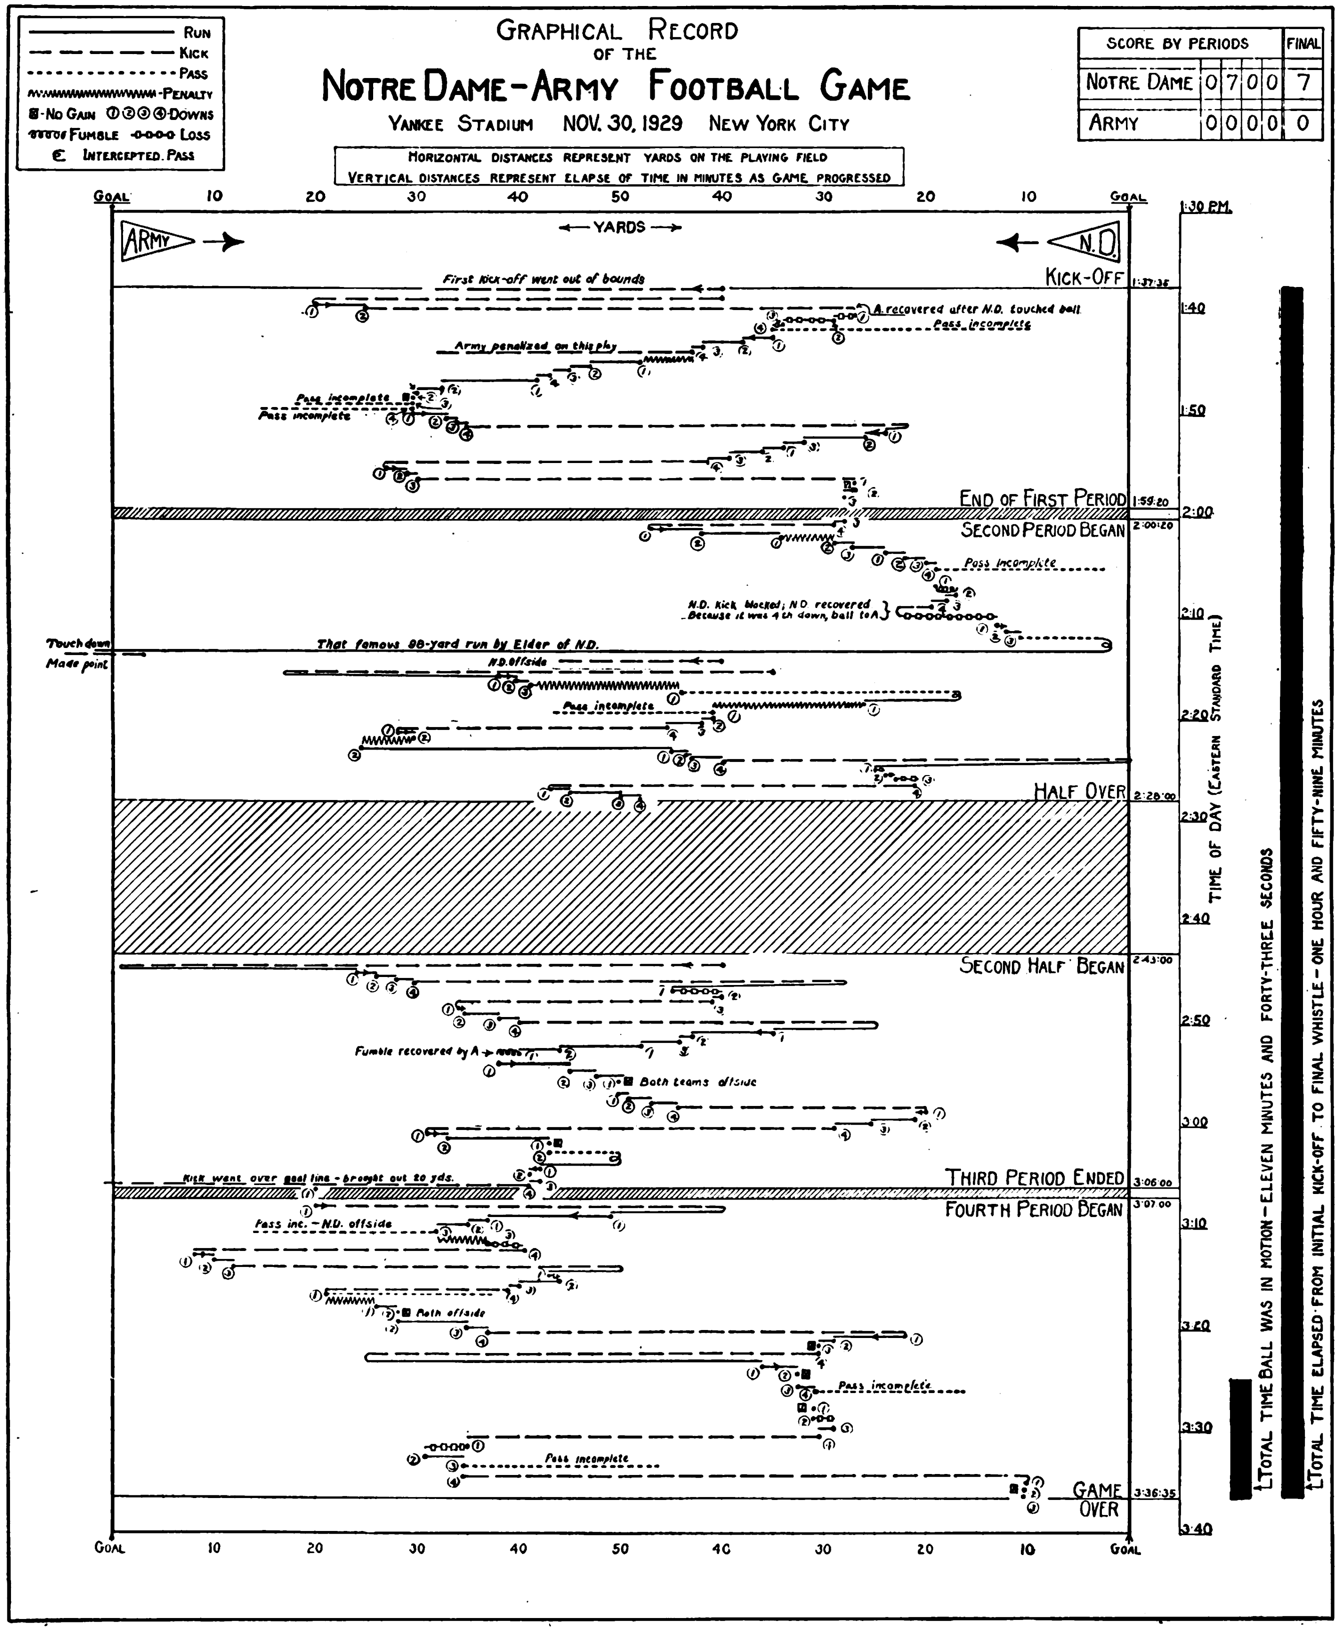
YOU pay at the rate of $24.25 per hour to watch football! It costs hundreds of thousands of spectators this amount for their amusement every autumn. The time the ball is officially in motion during an entire game—clocking each play with a stop-watch from the instant center snaps back the ball until the end of the play—totals the astoundingly short period of about 12 minutes. To be exact, the actual playing time in eight important games during the 1927, 1928, and 1929 seasons in which Notre Dame, the Army, Yale, Harvard, Princeton, Stanford, Ohio State, Columbia, Indiana, and Syracuse participated was an average of 12 minutes and 22 seconds per game. With your ticket costing you five dollars you paid at the rate of $24.25 per hour. If you were able to buy a ticket for three dollars, your hourly rate was only $14.55. If you were one of those spectators who paid sixty dollars a pair for the coveted pasteboards, figure out your own rate per hour.

The official playing time of one hour—four quarters of 15 minutes each—includes time for signals, formations, and shifts. The rest period between the first and second quarters, and the third and fourth quarters, is one minute; the time between halves is 15 minutes. Including periods for "time out," the total lapse of time from the initial kick-off to the final whistle, for the eight games mentioned, averaged 2 hours 20 minutes and 9 seconds.

TAKE the case of the Army-Notre Dame game at the Yankee Stadium on the last day of November, 1929—the game in which Elder of Notre Dame thrilled 83,000 spectators and many more thousands of radio listeners, when he intercepted one of Cagle's passes and ran 98 yards for a touchdown. For this game, many folk arrived half an hour before the kick-off and people were still leaving the stadium more than an hour after the final whistle, which blew 1 hour and 59 minutes after the kick-off. Hence some spectators spent about 3½ hours at the field to see the ball actually in motion less than 12 minutes (to be accurate, in this game it was 11 minutes and 43 seconds).

The time studies of the eight games proved that the period the ball is in motion during each play averages only 4½ seconds. This is based on a total of 1328 plays, all of which were carefully timed with a stop-watch reading to tenths of a second. As might be anticipated, some of the plays lasted four times as long as the average. And it was indeed apparent that the amount of spectator excitement was in proportion to the time the ball was actually in motion. The spontaneous cheers and yells were all concentrated in these very short intervals and all eyes were figuratively glued on the field.

On November 30, 1929, at the Yankee Stadium, in the second quarter, the Army had blocked one of Notre Dame's punts but Notre Dame recovered the ball. Since the play was on the fourth down, the ball went to the Army on Notre Dame's 13-yard line. Things looked fine for the Army. Two plunges by Cagle and Murrell netted a few yards, and then Cagle whisked a delayed pass over the left side of his line. Elder of Notre Dame rushed in boldly and, instead of playing orthodox football for a goal line defense and knocking the ball to the ground while covering receivers of the pass, he snatched



the ball from the air on his two-yard line, lost a precious split-second in regaining his balance, and then tore madly up the side line. Two Army men dove for him but missed—by a few inches. He ran unmolested until he reached the Army's eight-yard line when another West Pointer failed—by inches—to catch his elusive prey.

The fleet Elder raced over the goal line for a touchdown. But no one knew then that he carried the game with him. Carideo booted over a placement for the extra point, ending the scoring for the day. The crowd had been held spellbound. For 18½ seconds—the time of that play—they forgot the bitter cold. It was the longest play recorded in the eight games analyzed.

In the Army-Stanford game at the Yankee Stadium on December 1, 1928, there was another long play. Here also Cagle had a hand in it, but this time he did the carrying. The Army had the ball on their own 34-yard line. It was snapped back several yards to Cagle, who made a dazzling zig-zag run through the entire Stanford team, dodging tackler after tackler, to Stanford's 44-yard line for a net gain of 22 yards. It was a thriller. The play lasted 15½ seconds, the longest play of the game, and second longest in the eight games at which the time studies were made.

In the play which ranks third in point of time out of 1328, the performance of Christian Cagle of the Army is again encountered. This time it is in the Yale Bowl on October 22, 1927. With the ball on Yale's 48-yard line, Cagle received it about 12 yards back of the scrimmage line, and, by avoiding and throwing off Yale tacklers, down on his knees and back up again but never completely stopping, he carried the ball on another brilliant run of over 32 yards to Yale's 28-yard mark for a net gain of 20 yards. The total time of this play was 14½ seconds—14½ seconds bristling with thrills and gasps.

The average play in football—about 4½ seconds—hardly gives the spectators time enough to work up to a state of excitement. It remains for the long plays, such as the kind just described, to give the greatest thrills. It is these long plays that we like to see and read about. During each second of actual play the suspense is tremendous, and this is what really makes football the game it is for the spectators.

WITH the exception of the unusual plays such as those described, the punts consumed the greatest amount of time. They averaged about nine seconds, and the straight line plays three seconds. The average forward pass, counting those completed and also the incomplete, averaged about six seconds. The adoption of the pass has helped to spread the players more, and has served to increase the average time per play, thereby increasing the period of suspense and true excitement. Hence this change was a most important one from the spectator's standpoint—the standpoint that made half-million dollar gate receipts per game possible. Years ago the spectator saw little more than two struggling groups of 11 men each, pushing up and down the gridiron. The object was sufficiently apparent, but not the method of attainment. Consequently the game's power to draw paying spectators was not at its present height.

But what of the fact that the total time the ball is in motion during an entire game is only about 12 minutes? Shall we establish rules which will double or triple this period—the time during which the players are giving their every ounce of energy and the spectators are really getting the excitement they crave? No, it would not be wise to do so from either the spectators' or players' standpoint. Have you ever noticed that you are quite tired at the end of a football game, and particularly so if you are keenly interested in the outcome? As the ball moves back and forth on the field, you unconsciously push in the direction you would like to see the ball move. When the losing side cuts the air with "Hold 'em" they are unconsciously pressing their shoulders against an imaginary wall.

Students of public speaking and oratory tell us that a speaker who gets his audience extremely interested not only sways them mentally but also physically. It is said that the entire group of spectators at a football game actually moves with or against the ball, and by careful observation these waves of motion can be detected. Therefore, even though you may be paying at the rate of $24.25 per hour to see actual football, perhaps it is best for you that there is only 12 minutes of it. If you kept this tension steadily for an hour, you might have to be carried out of the stadium.

Cagle takes the ball

And now from the player's standpoint. A man running the 100-yard dash in 9-3/5 seconds is expending energy and moving at a rate which he could not maintain for 30 seconds. He would become so fatigued, if he tried it, that his pace would slacken before he traveled 300 yards. So it is on the gridiron. The men are giving every ounce they have, while a play is being executed, and it is undoubtedly good that the time per play *is* only a few seconds. Under the present rules, the players—all of them who have played hard—are usually nearly exhausted when the final whistle blows. The law of fatigue holds for everyone, regardless of his physique; the time for fatigue to take effect varies, of course, in the individual.

Consider the wear and tear upon human endurance during the game, when men line up for action 140 to 180 times. Little wonder that a rugged physique and heroic courage are required of the players. Hence it now can perhaps be better understood why, toward the end of a game, some of their performances are not quite up to standard.

Scientists tell us that when a muscle is stimulated, lactic acid is liberated in certain parts of the muscle. As this stimulation continues, an alkaline solution neutralizes the acid, which tends to relax the muscle. The process can continue until the available supply of alkali for neutralizing the acid is depleted. Then the excess acidity of the muscle stops its further activity and a state of complete exhaustion has been reached. Our whole voluntary muscular movement depends on this chemical reaction with lactic acid. There is a very definite limit to the extent any individual can use his muscles before complete exhaustion sets in.

The best way to win a mile run is to continue at a pace which will just produce exhaustion at the tape. If the pace is raised beyond this point, untimely exhaustion is certain to take place and the race is lost. Naturally, the longer the race the slower will be the average speed for each individual. Consequently, if the present rules and method of playing football results in near-exhaustion of the players at the end of the game, a change in the rules so there will be more actual playing time, without increasing the total time between the initial and final whistles, would mean a slackening of the speed and deftness with which each play is executed. Such a change would certainly not improve the game for the spectators.

A STUDY of the tabulated results of the eight games, with the number of plays and the time elapsed, provides some very interesting and instructive data. The number of plays per game averaged 166. The average number of plays per quarter varied between 40 and 43. This indicates that the proposed plan to play the game on the basis of 40 plays per quarter, in place of a definite time interval, will give us just as much football per game as at present. And, according to Mr. Harry R. Coffin of Harvard and other advocates of the new system, there are some very definite advantages. They claim the suggested period-by-play method has the following merits:

(1). It will eliminate the frantic use of the forward pass by the losing team during the final minutes of play.

(2). It will do away with any possibility of suspicious timing by officials.

(3). It will increase the interest of the spectators.

This system of playing was employed in the game between Brown University and Boston University in Providence on November 7, 1925, in which Brown won easily, 42 to 6. The consensus seemed to be that the score was too

A member of the *Scientific American* staff also visited Glozel, as did the author of the accompanying article, and made this and other photographs. According to one account the original "discovery" at Glozel was made while the young farmer, Emile Fradin, was plowing with cows. By chance, on the day of the visit, one of the Glozelians likewise was plowing with cows and within a few feet of the famous discovery site, which was at left just out of the picture

THE STORY OF GLOZEL— A CHAPTER IN CREDULITY[1]

By DAVID RIESMAN
Professor of Clinical Medicine, University of Pennsylvania

THOSE who have read something about Glozel may wonder why I speak of it here. Is it not a dead issue? No, for as a study of human credulity and as a commentary on the hot-headedness (or should I say pig-headedness?) of many men of science it will always occupy a prominent place in the history of civilization.

Although many are probably familiar with the main facts, I want to give a brief synopsis of the involved story. I say "story" advisedly for from the very outset the mystery of Glozel has formed a fascinating tale; very much in the genre of our best thrillers, with plot and counter-plot, gum-shoe detectives, and all the pertinent paraphernalia.

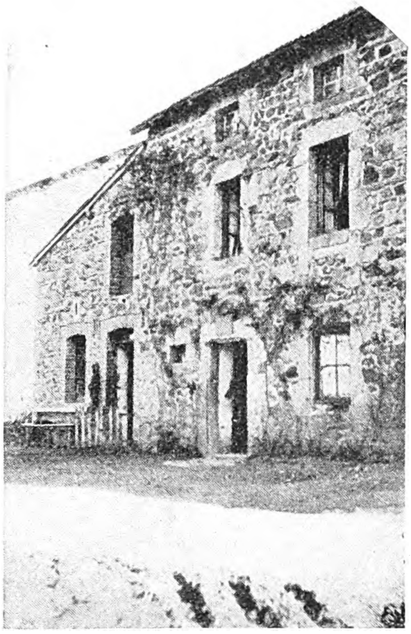
Glozel is a small hamlet of four farmhouses, about 15 miles from the famous French spa of Vichy. Emile Fradin, then a youth of 18 and belonging to an old local family, was one day working in his grandfather's field when a cow suddenly slipped into an unsuspected hole. Fradin went to investigate and found that the hole led into an oval pit containing a variety of remarkable objects—bricks, tablets, vases—which he gathered and as soon as possible showed to the village school mistress, Mlle. Picandet. The latter in turn showed some of the tablets to M. Clément, a school teacher in la Guillermie.

EVENTUALLY the news of the discoveries came to the ears of Dr. Albert Morlet, a surgeon of Vichy and an amateur archeologist. Thereafter Dr. Morlet and Emile Fradin together began to excavate at Glozel and brought to light more and more buried objects which they collected in grandfather Fradin's house and which Dr. Morlet described in detail in an endless series of articles in a literary journal, the *Mercure de France*. It was through this magazine—the *Atlantic Monthly* of France in more senses than one—that I became interested in the Glozelian discoveries. My interest was especially aroused by the claim of Morlet and others that an alphabet had been discovered at Glozel which antedated every other alphabet then known. I therefore decided while spending a vacation in the Auvergne to see Glozel for myself, but before doing so I determined to interview Dr. Morlet in Vichy.

At first he suspected me of being an archeologist but when in answer to a direct question, I denied the soft impeachment and proclaimed myself merely a doctor, he became cordiality itself and showed me his collection of Gallo-Roman and Glozel antiquities. He told me that he as well as others had been inclined to consider Glozel as belonging to the Magdalenian age because of the presence of harpoons and of stones engraved with reindeer and other animals long extinct in France, but further studies had led to the conclusion that Glozel was Neolithic. Dr. Morlet kindly asked me to

---

[1] Presented before the American Philosophical Society.



The little museum in the Fradin farmhouse. The crude sign mentioned by the author shows over the doorway. The picture was taken by a *Scientific American* staff member while perched on an "island" in the nearby manure-pile-quagmire, an entity which provides the cheery aspect from the typical French farmhouse. To see the exhibits he paid a few francs, as did the author of the accompanying article and, like him, was watched every instant by one of the Fradins; like a cat watching at a mouse-hole

stay over until the following day and dig with him and Professor Björn of Sweden, but I was unable to do so.

After leaving Morlet I motored, together with two American friends, to Glozel. Emile Fradin received us and at once offered to take us to the field of excavation. It was at the bottom of a deep ravine and was surrounded by a barbed wire fence. He showed us the original oval pit and the two tombs subsequently discovered. As it was raining hard and as the clayey ground was slippery, I declined his invitation to crawl into one of the tombs but asked instead to see the Museum. After paying two francs each we entered through a low door above which was a crude sign with the pretentious words, "Musée de Glozel," and found ourselves in a square low-ceilinged room with shelves on the walls and very primitive glass cases standing on the floor. The objects exhibited on shelves and in cases were astounding in number and variety—vases, tablets, engraved stones, ornaments (especially pendants), some pieces of glass, and harpoons, the last not nearly as artistic as those of Magdalenian age I had seen in Les Eyzies and at Laugerie-Basse.

Three articles attracted my special attention—vases or vase-like pottery ware having eyes, nose, and ears but no mouth, which Morlet has called death masks, explaining the absence of the mouth by assuming that the primitive makers wanted to express the silence of the grave. Secondly, a squarish object suggesting the female figure with a cylindrical projection from the forehead interpreted as the phallus—this Fradin told me was a bisexual idol; and most striking of all, clay tablets with graven signs looking in every way like alphabetical characters. I was struck by the clean red color of these tablets. When I spoke of this to Fradin, he explained it by saying that the soil in which the tablets had been found was such that it did not readily fuse with the clay and hence was easily brushed off. There were also some large casts of the human hand which differed from the imprints of the hands in the Spanish and French caves in having all the fingers present.

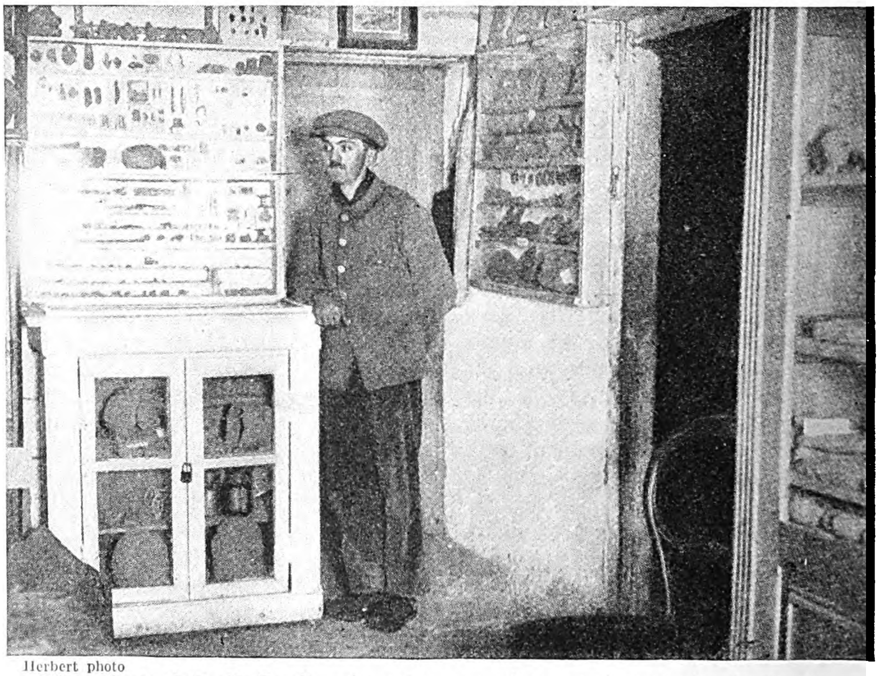
I offered to buy some of the articles, especially a tablet, but Fradin resolutely refused to sell. During the whole of our stay in the Museum, the grandfather stood silent and motionless in a doorway leading to an inner room.

The reputed discoveries of an alphabet dating back to Neolithic times, of which I had now seen the alleged evidence in abundance, created a tremendous sensation in informed circles. Altogether about 136 characters had been distinguished, representing every letter of the alphabet except the letter B.

Hitherto the credit for creating an alphabet had been given to the Phoenicians but the oldest known Phoenician record, found at Byblos a few years previous, dated back only to about 1300 B.C.; Sir Arthur Evens' baffling Cretan inscriptions to about 3000 B.C. If Morlet and those who agreed with him were right, then Glozel was truly what M. Reinach called it—one of the greatest archeological discoveries of all time.

ALMOST immediately after the first appearance of Morlet's reports, doubts began to be voiced about the authenticity of Glozel, though in the early period of the controversy there were perhaps as many scientists who accepted the discoveries in good faith as there were doubters. Soon the pro- and anti-Glozelians became personal and attacked each other with a vituperative vehemence and a destructive sarcasm for which the French language appears to be the ideal medium. Reputations were shattered, old friendships broken, and as one of the French dailies remarked—even butcher boys came to blows on the streets of Paris. In fact Mrs. O'Leary's cow did no greater damage to Chicago than Fradin's to the reputation of some French savants.

Before long the leading French pre-



Herbert photo

The principal, Emile Fradin, about 21 years of age at the time the site was investigated by the Committee. Although a humble peasant he had done better than average in school; he also was artistic and had done water color paintings. Perhaps it was a coincidence that the Glozel forgeries improved in technique from time to time as the schoolmaster Clément loaned Emile different pieces of literature on prehistory. The output of discoveries also corresponded with books given him by other interested dupes; it even accommodated itself in nature to the hopes and objections they expressed. Oddly, all periods of prehistory were represented by the objects discovered, from the Old Stone Age to historic times, and it is another coincidence that the illustrated textbook of prehistory in Fradin's possession covered the same scope. Picture taken in the museum historians with only an occasional exception began to deny the authenticity of Glozel and to declare the excavated articles to be forgeries. A number of Englishmen were likewise unconvinced. However, Dr. Foat, a London scientist, makes the categorical statement that "if the finds of Glozel are not authentic, it is equally necessary to consider as false all that I have seen in museums between London and Constantinople." Several Scandinavian, Belgian, and Portuguese scientists also supported Dr. Morlet, and a German, Dr. Wilke, in a recent article enthusiastically upholds the standard of Glozel.

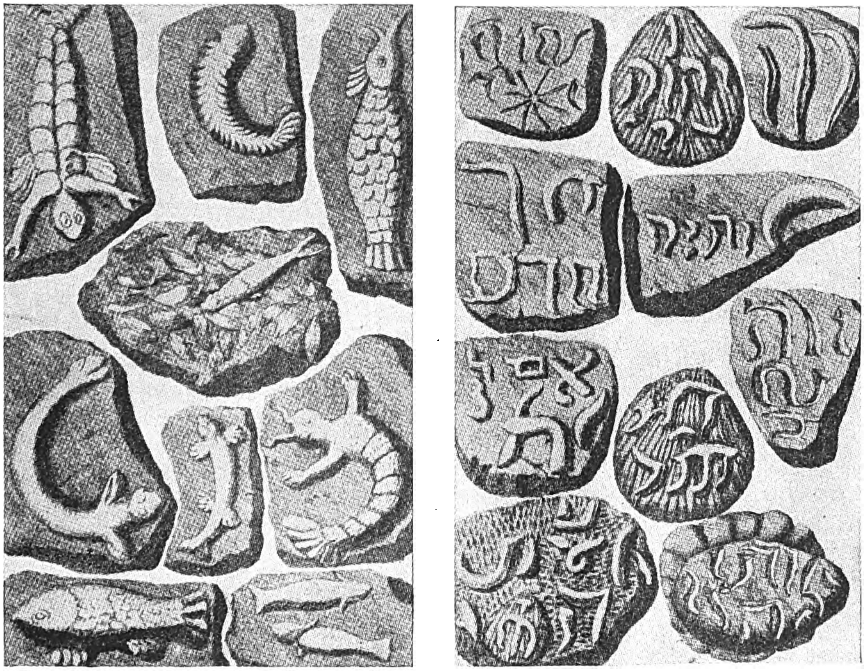
SCIENTIFIC AMERICAN staff photo

The actual site of the famous finds, at the lower end of a steep field above the valley of the Vareille stream. An attractive setting. The barbed wire fence around the site shows in the picture. It is easy for the tourist to reach Glozel; one goes to Vichy, where there are fine hotels, and hires a car to nearby Glozel

ARE Dr. Morlet's supporters right or is Glozel but one more of the long series of frauds that history recounts since Jacob imposed upon his father Isaac? Many will come to your minds—Thomas Chatterton, our own Dr. Cook, Constantine Simonides, the pretended author of the *Codex Sinaiticus*, the forger of the Mecklenburg Declaration, the Lincoln love letters in the *Atlantic Monthly*, the Tiara of Saitapharnes, and countless others.

One of the most interesting cases and the one having the greatest analogy to Glozel, if Glozel be a fake, is that of the so-called "Figured Stones of Würzburg." In the first half of the 18th Century there lived in Würzburg, in Bavaria, an ultra-pious physician named Johann Bartholomaeus Adam Beringer. He is not remembered for any great discovery or contribution to science, but for his share in a remarkable scientific hoax. At the time in which Beringer flourished an active discussion was going on as to the source and meaning of fossils. Although Leonardo da Vinci had understood their true nature—even Herodotus, 400 B.C. had a correct idea—the scientists of 200 years ago accounted for them as the result of "stone-making forces" of "formative qualities" or as growths from seeds. We may be inclined to smile, but with Dayton in Tennessee to chasten us, we can not throw stones at the Würzburg of two centuries ago nor at the Sorbonne which a hundred years later deprived the great Buffon of his chair because of his heterodox theories.

Beringer had committed himself publicly to the belief that fossils were the capricious fabrication of God, hidden by Him in the earth for some inscrutable purpose. His zealous maintenance of this fundamentalist position led some of the students, together with members of the faculty and wags of the town, to make numerous "fossils" of clay which they buried in the side of a hill where they knew the Professor was wont to search for specimens. Beringer, chancing upon these objects, was completely deceived. The jokers became bolder and buried the most extraordinary and extravagant figures their whimsical imagination could suggest. They fashioned tablets bearing inscriptions in Hebrew, Babylonian, Syriac, and Arabic, and buried them not far from the original spot. Beringer was overjoyed to find such abundant confirmation of his doctrines and forthwith in true German fashion proceeded to write an exhaustive treatise.



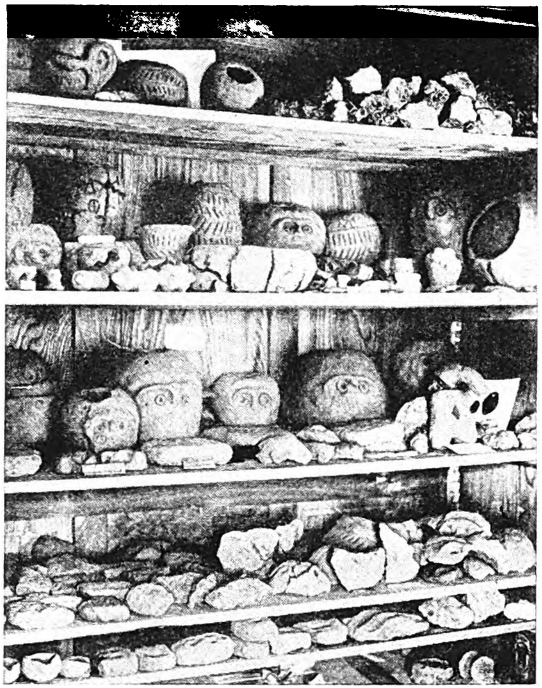
From the SCIENTIFIC AMERICAN MONTHLY, November, 1920. L. A. Hausman

Some of the famous Beringer fakes

THE wags now began to realize that they had gone too far. They expostulated with him and even told him the whole truth. Instead of believing them Beringer became more than ever convinced that the story his frightened colleagues told him was a ruse to rob him of the honor of his discoveries. No one could stop him. At great expense he published in 1728 the "Lithographiae Wirceburgenses."

Only too soon the shout of laughter with which the book was greeted brought the truth home to him. In chagrin and despair he exhausted nearly his entire fortune in a fruitless endeavor to suppress the edition and to buy up the copies already issued. He died soon afterwards, it is said, of a broken heart.

Is Dr. Morlet, like Johann Beringer, the victim of deception? Upon me personally he made the impression of an honest man. In certain quarters he was accused of fraud, for example, by the "Journal des Debats" and by the French Society of Prehistory. He promptly brought suit against them and won a



Herbert photo

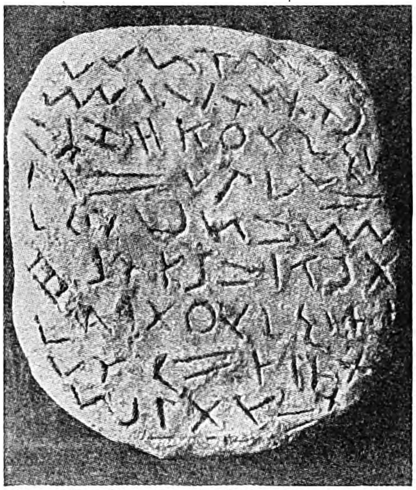
Exhibits in the museum of Glozel. Some are pots having eyes, nose, and ears but no mouth, as Dr. Riesman relates in his article. The "idol" to which he refers may be seen. Most of the objects in this picture are of pottery but the other finds have a wide variety— engravings on bone and stone, chipped flint and bone artifacts, and so on, representing a prodigious amount of industry on the part of (?)

verdict of 1000 francs damages. The defendants carried the case to the Court of Appeals at Riom, the native town of Willa Cather's lovable archbishop. In confirming the verdict, the Court gave expression to an amusing quibble. It held that Morlet, being a surgeon by profession and only by avocation a prehistorian, was not injured in the eyes of his real colleagues but only as an amateur archeologist. But as the defendants had not actually proved fraud, they were declared guilty though the fine was reduced to one franc and costs.

ANOTHER humorous episode might be mentioned. Regnault, President of the French Society of Prehistory, sued a Monsieur X because he, Regnault, had been compelled to pay the sum of four francs to see a collection of fake objects. As part of this legal action, the police of Moulins broke into Fradin's premises and took away a number of objects which were afterwards submitted to the public expert, M. Bayle. The latter reported that the tablets were of recent manufacture. Pieces of clay from a tablet crumbled readily in water; hence it was not conceivable that the tablets could have resisted the moisture in the ground had they been there for many years. Furthermore, a bit of grass picked out of a piece of earthenware showed under the microscope the vegetable cells, and some of the bone instruments still contained marrow. Bayle was soon afterward shot to death by one Philopponet against whom he had testified in court.

The Fradins themselves brought suit against M. Dussaud, member of the Institute, who in a trenchant brochure had called them fakers.

Let us now delve a little more deeply into this mystery so that we may understand better the basis of the controversy. The first serious doubt as to the authenticity of Glozel was based on the heterogeneity of the articles in Fradin's museum. How could one explain the presence of so many disimilar and unrelated objects—the 2000 or 3000 at the time of my visit have now grown into 5000 in one small field of excavation. No other archeologic site offers a parallel.



From "Glozel" by Dr. A. Morlet

One of the many inscribed tablets. After a fancied resemblance to the old Phoenician alphabet was mentioned the subsequent "discoveries" oddly came more and more to resemble Phoenician. Later, M. Bayle, the "Sherlock Holmes" of France, found minute strands of cotton colored by aniline dye in one of the clay objects. Perhaps, however, the apologists for the Glozel incident would say this proved that Neolithic man of Europe (5000 to 11,000 years ago) understood the synthetic chemistry of dyes

Morlet answered this by saying that Glozel was a *Champ des Morts,* a cemetery; and that, as among many primitive peoples of later times, everything belonging to the dead had been buried with him. C. Jullian, who considers Glozel a Gallo-Roman station, accounts for the multiplicity of objects by the assumption that Glozel was a sorcerer's sanctuary. He has added greatly to the gaiety of nations by attempting a full translation of the inscribed tablets from the published illustrations. Dr. Morlet showed me with much amusement a crack in one of the tablets which Jullian had translated as a character.

Aside from the puzzling complexity of the collection, it has been pointed out that the tablets first exhumed bore fewer and less perfect characters than the later ones. Further, as soon as some one had made a criticism, the objects next exhumed were free from the criticized defect. Quite often certain features appeared that could be traced directly to scientific articles published shortly before. These facts seem, of course, very significant. Moreover, the scratches on stones, whether representing animal figures or alphabetic characters, were without the patina covering other parts of the stones, suggesting a recent production. Much was made of the penetration of roots into vases or tablets; but upon examination these roots were not found to be properly fossilized, which would have to be the case had the objects been in the ground for long ages. The utensils—harpoons, hand axes, scrapers—are far less artistic than those in other Neolithic stations. Vayson de Pradenne and Abbé Breuil indeed contend that none of them could ever have been used.

DR. MORLET and his chief supporter Van Gennep did their best to answer all these objections. The former at the height of the verbal battle-royal made a request for a governmental commission which was speedily granted, but when he found that a bitter anti-Glozelian, the well-known archeologist Capitan was a member, he objected and the Commission was never sent. Eventually, at the International Anthropological Congress at Amsterdam an International Commission was formally appointed to investigate Glozel. The Commission consisted of Absolon, Director of the Archeological Museum of the State of Moravia; Bosch Gimpera, Professor in the University and Director of the archeological work of Barcelona; the Abbé Favret; Forrer, Director of the Prehistoric and of the Gallo-Roman Museum at Strassburg, Miss Dorothy Garrod, Member of the Royal Anthropological Institute and of the French Prehistoric Society; Hamal-Nandrin, Lecturer on Prehistory in the Museum of Liège; Peyrony, Director of the Museum of Les Eyzies; and Pittard, Professor of Anthropology in the University of Geneva. Absolon was prevented from taking part in the work of the Commission.

After spending three days at the site the Commission issued a unanimous report which was kindly sent to me by Miss Dorothy Garrod. This report states unequivocally that the articles are for the most part of recent manufacture and have undoubtedly been planted in the ground by some one whom the Commission does not name; and that Glozel is neither prehistoric nor authentic. Vayson de Pradenne in a devastating brochure in which he declared the Glozel finds fakes, also accused no one by name but put the blame upon the "Esprit de Glozel;" in other words upon a fairy.

ONE might think that with the leading French, English, and American scientists—Peyrony, Pradenne, Abbé Breuil, Sir Arthur Evans, Dussaud, and, I believe, Professor MacCurdy—arrayed against Glozel, and with the destructive judgment of the International Commission, Glozel would cease from troubling the scientific and the lay mind. Though all due obsequies have been performed, Glozel refuses to remain in its sepulchre, and the literary battle continues. Dr. Morlet constantly sends me newspapers and pamphlets[2] and a distinguished pro-Glozelian of Belgium, Professor Tricot-Royer, has just supplied me with his defense of Glozel which is particularly interesting because Professor Tricot-Royer was present during the visit of the International Commission.

What keeps Glozel alive? First we have the fact that when men take sides in print they are loathe to recant, fearing ridicule—the more untenable their position, the more stubborn their resistance.

Secondly, six months after the International Commission's visit Dr. Morlet called together a Comite d'Etudes consisting of Dr. Foat, Bayet, and Tricot-Royer of Belgium, Reinach, J. Loth, W. Loth, Van Gennep, Deperet, Ajcelin, Roman, Audollent of France, and Soderman of Sweden; all sympathetic to Glozel. At their meeting they pronounced unanimously in favor of its genuineness.

Another reason is found in the attitude of a group of French and German scientists who are opposed to the traditional belief that *ex oriente lux*—that civilization is of oriental origin. The alleged Neolithic alphabet of Glozel and similar finds at Alvao in Portugal are grist to their mill.

In addition quasi-political factors have entered into the controversy—Fradin an obscure peasant, Morlet a provincial doctor without much influence, have a definite appeal for the proletariat and for a large section of the press.

And finally, it must be remembered that the Academicians are not always right—that they ridiculed Pasteur and Boucher des Perthes; and even Koch and Lister met a similar fate in the beginning.

All these elements co-operate to keep the spark of life in Glozel. Within the past few weeks the publication of an exhaustive treatise by Dr. Morlet has been announced.[3] This, however, I fear, can throw no new light upon the subject.

Herbert photo

"The International Commission" of scientists making an official investigation

As a detective tale the story of Glozel remains unfinished and will remain so until a Sherlock Holmes discovers the person or persons who manufactured the articles and put them in the ground. What was his motive? How are we to explain the extraordinary industry that has fashioned 5000 or more articles, and how is it that he, the "Esprit de Glozel," escaped detection in a community of 29 souls where everyone knows everyone else's business. Or how, if there are witnesses to the dark deed, can we explain an unbroken neighborly silence extending over a period of six exciting years?

Herbert photo

Dr. Morlet demonstrating his claims at the site, before the members of the "International Commission" of investigation. Vayson de Pradenne, president of the Prehistoric Society of France, in *Antiquity*, characterises him thus: "Still young and endowed with wild energy, with an inflexible resolution and a naïve and immoderate self-esteem; devoid on the other hand of competence and of the critical faculty, he threw himself whole heartedly into the fray"

---

[2] Similarly, the enthusiastic Dr. Morlet has sent clippings, newspapers, and pamphlets, and his publisher a book by the doctor, to a member of the *Scientific American* staff who, when passing through Vichy, attempted to see him, but who was given to understand by some one within the Morlet household that the doctor was seeing no one, and who left his card. Residents of Vichy suggested that the doctor was finding it expedient to "hide out" at the time, until the legal storm might blow over. —*The Editor*

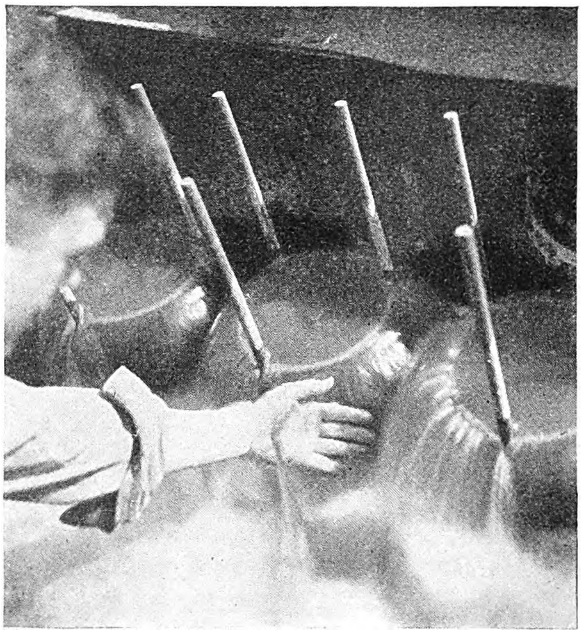
[3] "Glozel," by Dr. A. Morlet, a copiously illustrated work published by Georges Desgrandchamps, 23 rue Boissonade, Paris (XIVe). The especially interested reader will find a 20-page article entitled "The Glozel Forgeries," by A. Vayson de Pradenne, President of the Prehistoric Society of France, in the journal *Antiquity* (Gloucester, England), Volume 4, No. 14. Several *Cahiers de Glozel*, some by Dr. Morlet in his own defense, have been published by Paul Catin, 3 rue Sabot, Paris (VIe); other matter, by Octave Belin, 26 rue Pasteur. —*The Editor*

BY-PRODUCTS FROM INDUSTRIAL WASTES

By ERNEST W. STEEL

Professor, Municipal and Sanitary Engineering,
Agricultural and Mechanical College of Texas

A STATE legislator not long ago seriously advocated the abolition of the state health department, and by inference all health departments, on the ground that at best they were wasters of public funds and nuisances. Persons of the same opinion may be surprised to learn that the complaints of health officials have stimulated industries to reclaiming large amounts of valuable materials which were wasting unheeded into streams and municipal sewage.



Clear overflow from equipment that reclaims an appreciable amount of wood fiber from the discharge water in a paper plant. Where this is not in use, the discharged water pollutes streams and kills fish

The liquid wastes of many industries are of such a nature that they cause serious troubles in streams and at municipal sewage treatment plants. In the streams, fish are killed and the water is made unsuitable for water supplies and recreational uses. At the sewage treatment plants, the biological action may be upset by antiseptic substances, or the enormous volumes of organic matter from the industry may overload the plant to such an extent that it must be increased in capacity or must bypass untreated liquid into streams. Accordingly, many industries have in the past few years been notified by cities and state health departments that the burden of waste treatment must be assumed by the industry, either completely or in large part, before final discharge into sewers or streams is permitted.

SUCH notices have been received with apprehension by the industries concerned until study of the problem showed that what appeared to be a liability was capable of returning profits. An example of this is the Corn Products Refining Company of Argo, Illinois, which manufactures starch and other corn products. Final disposal of its liquid wastes is a matter of much concern to the Chicago Sanitary District. The chemists of the District found that the wastes of this plant were so large in volume and contained so much organic matter that they were equivalent to the sewage of a population of 800,000. The treatment of this waste was, of course, too great a burden to place upon the taxpayers. The alternative appeared to be the construction by the company of a special treatment plant, estimated to cost 2,900,000 dollars.

Investigation of the plant with respect to sources of the waste indicated that a considerable portion of valuable product was escaping into the waste pipes through poor control of certain processes. Improved mechanical equipment and weeding out of heedless operators remedied this. Result: a 10 percent decrease of the waste, and an increased output.

The greater portion of the waste, however, was composed of the liquor in which the corn is first steeped and softened. By installing comparatively inexpensive equipment the steep-water can now be evaporated to such a consistency that it can be used for making a stock feed. Result: an annual return of 500,000 dollars which was formerly lost through waste, and a reduction of volume and concentration of the plant waste from a population equivalent of 800,000 to about 50,000. The present wastes owe their strength to the organic matters distilled over in the vapors of the steep-water during the concentration process. It is possible that some valuable constituents can still be extracted, and further experimental work is being carried on.

Another industry which has frequently been embroiled with health departments is that of coke making. Coke is made by distilling coal, and many valuable products are in the distillate. After these are removed, there remains a liquid containing tar acids and phenol, or carbolic acid. The latter is especially troublesome, particularly if the stream or lake which receives the wastes is a source of municipal water supply within many miles of the point where the waste enters. If the water supply is chlorinated, the phenol taste is particularly bad. The disagreeable medicinal taste of the combined phenol and chlorine has been noticed when the water contained only 1/25 of an ounce of phenol to a million gallons of water. Methods of recovering phenol from the still-waters have been developed and now it is possible to extract it and obtain salable phenol in amounts sufficient to pay the cost of extraction.

THE phenol problem has also received much attention on the part of scientists of France, Denmark, and Germany to prevent pollution of the relatively small rivers of those countries. From their studies comes a new and startling solution. It has been found experimentally that if the phenol-containing liquid is applied to the soil, the injurious constituents are converted into ammoniacal compounds which can be utilized by soil bacteria and act as crop fertilizers. The conversion process takes about two weeks. Previous to the change, of course, the phenol is injurious to plant growth and accordingly the liquid must be applied a proper length of time before sowing. A very important advantage claimed is that, while the phenol is still active, it will destroy weeds and injurious insect larvae present in the soil. The combination of fertilization and weed and insect killing properties may change entirely our methods of disposing of this troublesome waste.

In the bituminous coal mining regions of the eastern states there have been many disputes between mine operators, cities, state health departments, and fish conservation commissions. The drainage water of coal mines contains little or no dissolved oxygen and hence will not support fish life. It will so lower the oxygen content of streams into which it discharges that fish cannot live in them. Mine wastes are even more troublesome because of the acid and other chemicals which they have dissolved out of the coal beds. Acid is a killer of fish and in addition makes the polluted streams black and evil smelling and unsuitable for municipal water supplies. The only remedy found so far has been to require owners of mines to seal up those abandoned workings from which drain water trickles down the hillsides. Lately, however, the Kaplan process is reported from West Virginia. It consists of adding to the mine waste a complex chemical which combines with the undesirable chemicals to form a useful blue pigment, which has a far greater value than has the chemical reagent added. Appropriately enough, the new pigment has been called Monongahela blue.

IN all of the forested states are mills engaged in turning wood into various grades of paper. The process requires much water—to break down or digest the wood into fiber, to wash it after digestion, and to convey the fiber around the plant through pipes and channels. Indiscriminate discharge of the wastes has changed streams which traverse regions of great scenic beauty into black and evil-smelling open sewers. Fish are destroyed. Regions which are ideal for camping, fishing, and vacationing are spoiled.

The paper industry, however, after exertion of much pressure by state health and game officials, is doing much to remedy the situation. Study of plants indicated that much of the conveyor water with its valuable fiber was escaping accidentally or through remediable carelessness. Some fiber unavoidably escapes from the paper machines. This waste is being reclaimed by special patented sedimentation processes which allow return to the plant of the rescued stock. At some plants the water, after removal of fiber, can be returned for further use. This is especially profitable where the water must be pumped long distances from the original supply or must be filtered or otherwise treated before it can be used.

The wastes from the digesters and washers contain much chemical matter that is especially undesirable in streams. The chemicals need not be lost, however, and most paper plants are now installing systems for evaporating this waste. After evaporation, the residue is burned and the chemical is regained in a modified form. The magnitude of this procedure is indicated by the fact that 7000 gallons of water must be evaporated for each ton of pulp manufactured.

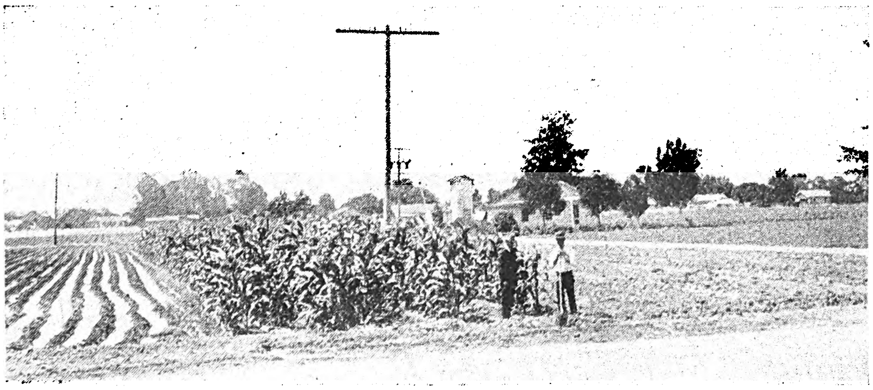
Most troublesome of all problems to the paper industry is the disposal of the highly corrosive liquid wastes from the sulfite pulping process. Some progress has been made by some plants which are converting the waste into adhesive and other by-products having commercial value. Experimentally, investigators have found that alcohol, road binders, linoleum cements, dyes, fertilizers, and many other products can be made. The difficulty is that sulfite waste is produced in such enormous quantities that if all of it were converted into by-products, the market probably could not absorb them all, although alcohol manufacturing may possibly be the final solution.

THE textile industries also produce troublesome liquid wastes. Foremost among these in difficulty of treatment is wool-scouring waste. It contains much dirt, wool fiber, and grease. Wool fibers can be caught on fine screens and returned to the plant. Grease is highly undesirable at sewage treatment plants, and wool-scouring establishments are required, or at least encouraged, to remove all grease before discharging wastes into sewers. After removing grit and heavy dirt, the waste is treated with sulfuric acid which changes the grease into a thick scum and sludge easily removable from the liquid. The scum and sludge are then pressed and the grease is squeezed out. The grease so obtained is very largely lanolin, which is much used as a base for medicinal ointments. The cake that is left behind after grease extraction has some value as a fertilizer.

The most frequently encountered waste is that from plants which handle milk or manufacture milk products. At sewage disposal plants, milk waste sours and upsets the normal bacterial action. Discharged directly into streams, the usual results of stream pollution, nauseous odors, and killing of fish follow. The whey from cheese-making plants is especially troublesome in this respect. Whey has been found to be a valuable hog food and is returned to farms for that purpose. The ordinary milk wastes contain much casein. It can be precipitated by small amounts of sulfuric acid and the resulting thick sludge fed to chickens or hogs. Since casein has many uses in the industries and can be converted into glue, or into poker chips and other artificial ivory objects, it is highly probable that the large condensed milk and cheese factories will eventually salvage this material.

IN spite of the progress which has already been made, stream pollution by industries is a rapidly growing problem. This is due not only to the increasing industrialization of the country but also to the tendency of industry toward decentralization. Formerly industries grouped in certain regions or in the large cities. Their wastes, together with the domestic sewage of the large concentrated population, were discharged into the large rivers, lakes, or harbors where centers of population naturally developed. Comparatively few bodies of water, therefore, were grossly polluted. Now, however, factories of all kinds are scattered over the country. Advantageous as this may be to the industry and to its employees it has been harmful to many streams.

Possible damages to streams should be a matter of concern to all industries contemplating relocation. Town and city officials who are tempted to bid eagerly for a new industry would do well to inquire into the nature of the wastes which it may unloose upon the countryside. Should deleterious wastes be features of the particular manufacturing process, an agreement as to their disposal may prevent unpleasantness. Finally, where wastes are already causing trouble, scientific inquiry, carried on by the industry in co-operation with the proper governmental authorities will probably bring about a solution to this problem, the growth of which is measured by the growth of industry.



Milk wastes discharged into streams cause harmful pollution. This photograph shows creamery wastes being used to irrigate a farm

THE YOUNG GIANT: NATURAL GAS FUEL*

THERE was a slight trembling as, 480 feet below the surface, the crude string of tools dropped into a pocket. The trembling became a dull rumbling, like distant thunder, and the rumbling a rapidly swelling roar until there burst from the mouth of the rough casing a mighty column of mud, oil, and water, borne on the driving fist of a tremendous pressure that rocketed tools and equipment high into the air.

The drillers cheered. At last, after two years of slow, plodding effort, they had struck oil. They were rich.

But their cheering was short-lived. The dark stream soon thinned out and then disappeared altogether, leaving only a colorless substance escaping into the air and a roaring noise that seemed to mock them. The well was a failure, it seemed, for they had struck, not oil, but a gas pocket.

For days the terrific pressure blasted millions of cubic feet of natural gas into the atmosphere in an ignorant waste that would make the gas producer of today weep, while the owners of the well stood around disconsolately and wondered if any oil would follow. Finally, after weeks of waiting, they gave up hope. Some months afterward the roaring gas jet was ignited and the towering torch lighted the countryside for miles around, symbol of a later day when natural gas would be burned for heat and power in home and industry.

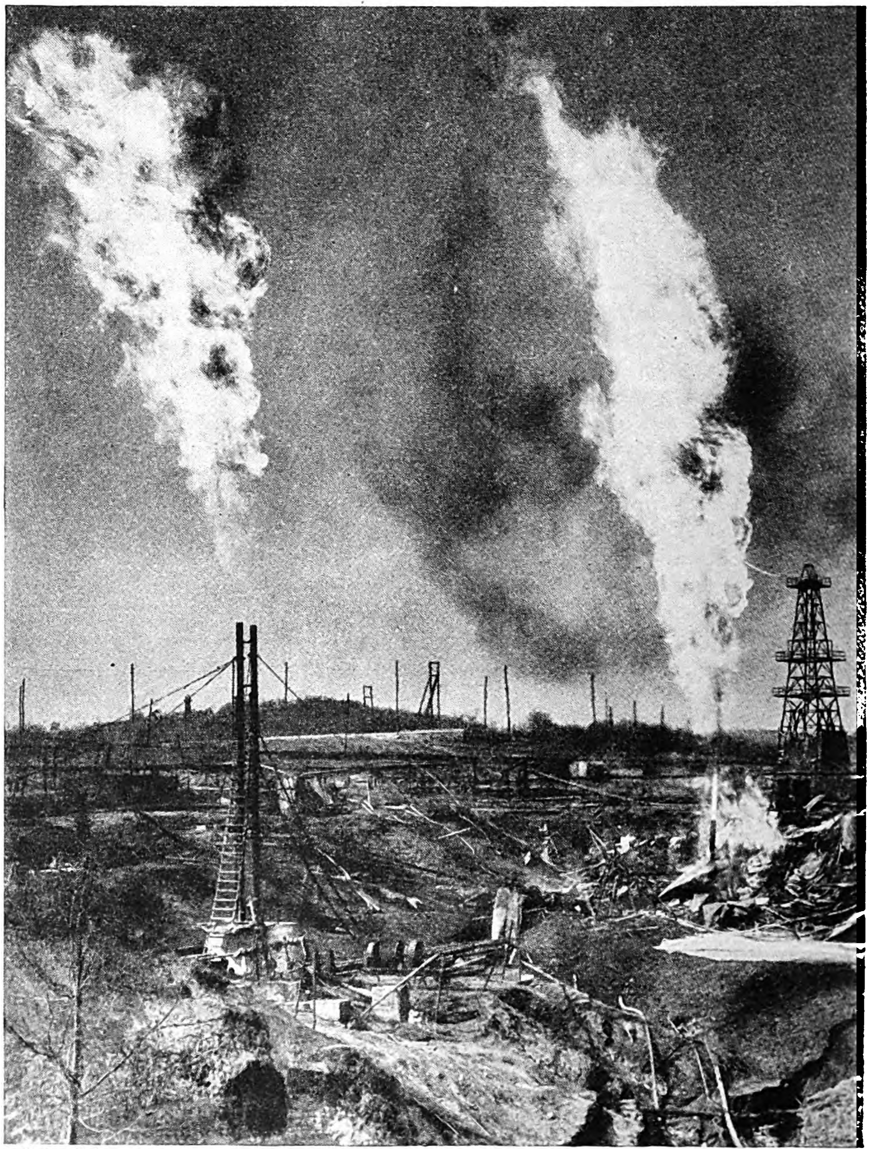
THE above incident, which is typical of hundreds, probably, in the early boom days of the petroleum industry when oil was the gold men sought, actually took place at West Bloomfield, New York, in 1865.

As a matter of fact, natural gas is as old as petroleum in the experience of men. But because it was often practically invisible, ignorance shrouded this masquerading giant of power in a veil of superstition for many centuries. The ancient oracle of Delphi is said to have been situated near natural gas fissures. According to the story, a shepherd noticed that some of his goats wandered about queerly in a certain spot. Going over to investigate, he felt a certain lightness coming over him. Villagers came at his call and immediately experienced the same dizziness, talking in disjointed sentences. So they concluded that a god must live there who had cast a supernatural spell on the place, and accordingly built a temple on the spot.

The Chinese and Japanese may have been superstitious too, but apparently they didn't let their fears blind them to the useful nature of the product. Plenty of evidence has been found to show that these people burned natural gas and even transported it in crude lines made of bamboo or animal intestines. History is full of similar instances. But it was not until 1821 that the first gas well was sunk near a spring at Fredonia, New York—a good 38 years before Colonel Drake's historical oil well at Titusville. Like petroleum, however, gas had been discovered before while boring for salt.

Between superstition, ignorance, and, later, mechanical difficulties of production and transportation, it has taken man many centuries to tame the "wild spirit" of prehistoric times and put it to work for him. A natural gas pipeline map of the United States would show a connecting maze of gas lines in many parts of the country, yet not so very many years ago natural gas was only a by-product, a waste that had to be blown off sometimes before the oil came; or, at best, something that held the pressure which carried petroleum to the surface and saved a certain amount of pumping.

Natural gas operations represent literally an "industry within an industry." Yet the business of producing, transporting, storing, and marketing this



Ewing Galloway

A scene typical of many during the early days of oil well drilling: a well comes in with a roar of gas which, accidentally becoming ignited, is wasted

product differs widely from that of petroleum in many respects.

Consider production. In appearance, a gas field looks very much like an oil field to the layman. There are much the same derricks, tools, toolsheds, and pipelines. But the problem of pressure is much more vital in gas operations. The producer cannot put his well on the pump, as the oil man can, when the pressure fails. And the first well down in a new field, naturally enough, gets the full pent-up pressure of the entire area, which may be considerably reduced by the time other bits reach the gas-bearing sand. On the other hand, pressure is not always an indication of how prolific a field is likely to prove. Many an apparently promising area has come suddenly into being, yielded abundant stores for a year or more and then just as suddenly gone dead.

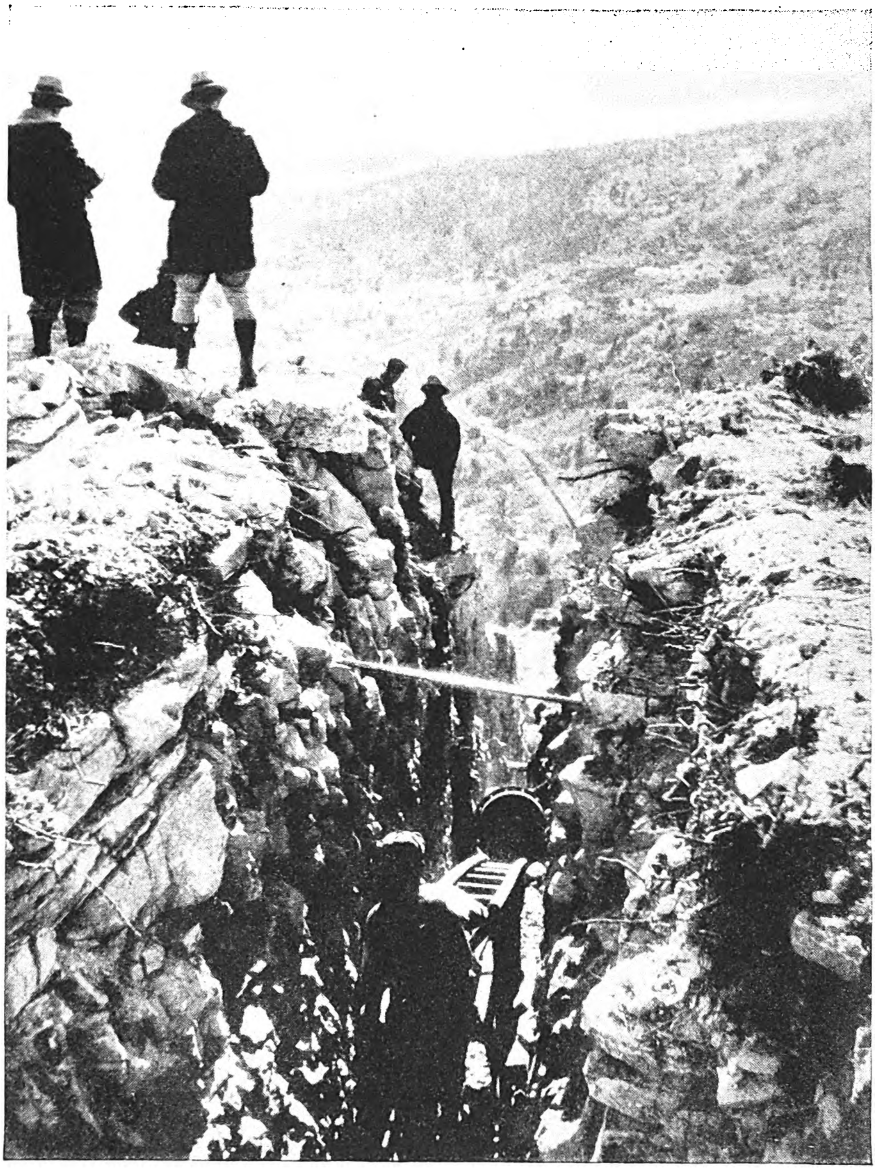
Just as difficult is the problem of transportation. Where the oil man can ship his product by pipe-line, tanker, tank car, by barge, in barrels, or in any other way that emergency may suggest, the gas producer has only one channel of transportation—pipe-lines.

ONE of the most perplexing problems, however, which the industry has had to face—one which has largely been solved by developments entirely without its sphere—has been that of marketing. As might be expected, the first use of natural gas was in the home. In areas within reasonable distance of producing fields, natural gas could be supplied cheaper, very often, than the manufactured product. But here the industry was up against the problem of seasonal demand. Inevitably, extremely cold days multiplied the drain on his pipe-line system eight to ten times. Just as surely, morning and evening drew heavily on the lines, with consumption comparatively slack during the day. Natural gas can not be manufactured as needed. If the supply is too great, the product must be kept in the ground. If it runs short, the producer has to find new fields if he expects to stay in business.

Let's see what the industry has done to get around these obstacles.

First of all, there is far less waste than in the old days. Seldom does one see gas blown wantonly into the air from wells sunk into strata containing both gas and oil. The former is far too useful for re-pressuring oil sands—to say nothing of its commercial value—to throw away. Next is the matter of storage. The producer today has found that by far the most efficient and economical method of storing his product is right in the ground from which it came.

It has been the widespread growth of industry and manufacturing, however, which in the last analysis has changed the whole outlook of natural gas markets, given the producer an incentive for seeking new and richer fields, and economically justified the huge capital expenditures for lines from producing areas to industrial centers.



A rugged ten miles of scenery on the Denver gas line. In distributing gas from the fields, pipe-lines must be laid across mountains and through rivers

The United States is the greatest manufacturing nation in the world. Nor are the factories and industrial plants of the country now crowded into the northern states, as they were in former years. Today industry thrives in the south and west where formerly cotton pickers crooned in the sun and cattle roamed the plains. The natural gas business was quick to realize that here was a chance for mutual development. Its new customer would consume gas in large quantities, and at a comparatively uniform rate throughout the year. In return, the industry could offer him the cleanest fuel known to science with a high heating value of approximately 1000 B.t.u. per cubic foot, one that burns completely with no smoke or ash.

It has been estimated that there are over four billion dollars invested in the United States today, in the various producing and marketing areas scattered over the map, with thousands of miles of trunk and feeder lines, like spider webs in a garret. The output of energy from natural gas burned in the United States during 1929 was estimated to be equivalent to 527 billion kilowatt hours—nearly six times the total production of electricity for the same period. Known fields, with improved methods of computing reserves, give the industry almost unlimited supplies of raw material to work with. Texas Panhandle and the Monroe-Richland field alone can assure the industrial markets of the south and middle west of adequate resources for many years to come. Yet all these assets of supply, scientific methods, and expanding markets which Nature, their own inventiveness, and evolving conditions have given the men engaged in natural gas operations, might well prove to be so many stones, yielding no profit, were it not for one thing. The industry has found to a remarkable extent the way to real practical co-operation.

The natural gas business is not a one-man job, so to speak. The product itself is easily susceptible of waste; and producing areas, unless scientifically drawn upon, may lose much gas that never reaches the market. The laying of lines from field to market involves the expenditure of millions of dollars. In distributing the product to numerous towns along the right of way, as well as at the destination of the main line, countless local interests have to be taken into consideration.

Here, then, is an invaluable natural resource. To bring it from its age-old prison, thousands of feet under the earth, to the burners of various industries in widely separated parts of the country, calls into play hundreds of varying interests. Producer, landowner, engineer, municipality, consumer, scores of others, all have their rights; all must be considered. The tiniest cog can wreck the whole machine.

So the tremendous projects which have been successfully swung by the natural gas industry speak volumes for the fine degree of co-operation, orderly exploitation, and scientific development within its ranks.

The eastern section of the United States was the cradle of the natural gas industry in America. From the producing fields in West Virginia, Pennsylvania, and east Ohio has crept a maze of pipe-lines carrying fuel to the scores of industrial centers throughout that territory, until the map takes on the appearance of a jig-saw puzzle. Today those eastern subsidiaries of the Standard Oil Company (N. J.) operate something like 16,000 miles of main and feeder lines, with estimated distribution for 1930 of 104 billion cubic feet of gas.

Yet, even before eastern markets for natural gas had developed to their present proportions, the wildest gambler would never have undertaken to pipe the product to Baton Rouge, St. Louis, or any of the great centers of the south or middle west. The industry would have laughed at him. And—at that stage of development—it would have been right. Production methods were not as scientific as they are today. Nor were the compressors and lines of a quarter century and more ago as efficient as they are today. Men had no way of estimating with any degree of accuracy the potential output of a field, and the industry could hardly be expected to gamble an investment which it would have to carry 10 or 20 years on the chance that the elusive material in the sands under their wells would last that long. Finally, many of the markets in the south and middle west were not yet ready for natural gas.

So fate played a fortunate trick on the industry in hiding from geologists the prolific Monroe-Richland and Panhandle fields until a time when the engineer and consumer had prepared the scene for more extended use of their treasures.

Panhandle is undoubtedly the greatest natural gas producing field in the world today, with the Monroe-Richland area not far behind. It is almost impossible to estimate how much gas lies locked in the sands of these two fields, needing now only the turn of a valve to release it. But a fair idea may be gained from the fact that the combined capacity of lines already tapping them runs up to several hundred million cubic feet daily.

Amarillo field alone, in the Panhandle district, was thought two years ago to hold some 10¼ trillion cubic feet—enough to keep a line of 100,000,000 cubic feet per day capacity operating continuously at full force for nearly 300 years. That this great natural wealth may be expected to last many years is plainly testified by the investments of many millions which have gone into the construction of 300-, 400-, and 500-mile lines.

There are three main projects through the south and southwest in which Standard Oil Company (N. J.) subsidiaries have an interest, the most recent being the Mississippi River Fuel Corporation's 431-mile line from Monroe to St. Louis. In addition to the main line, branches will make the gas available to industrial plants in Crystal City, Missouri; and in East St. Louis, Granite City, and Alton, Illinois. Other industrial consumers within reach of the main line through Louisiana, Arkansas, and Missouri also will be served.

In 1927, the Interstate Natural Gas Company completed its line from Monroe to Baton Rouge. The Interstate also contracts to furnish gas from its Monroe reserves for the Southern Natural Gas Corporation's line to Birmingham, Alabama; Atlanta, Georgia; and various adjacent points, as well as to several other interests. Over in Texas the Canadian River Gas Company transports the fuel from Amarillo Field, in the Texas Panhandle district, to Clayton, New Mexico. Here it is purchased by the Colorado Interstate Gas Company (N. J.), and brought to Pueblo and Denver, Colorado, as well as to other towns along the way. In addition, the Colorado Interstate supplies gas for a line north from Denver to Fort Collins.

And so the natural gas industry has grown. Once a "wild spirit," represented by mysterious pillars of fire that issued from fissures in the earth to terrorize natives, then an incidental by-product of oil drilling, natural gas today not only has found its way into homes in many districts, but more and more is replacing its brothers, fuel oil and coal, for numerous industrial purposes. Glass, ceramic and cement plants, steel mills, brick, lead, enamel ware and vitrified clay manufacturers, oil refineries, power plants, and all other industrial users within reach of existing or projected lines are giving ample illustration of the value of the product.

To what extent new producing areas, further improvements in drilling and transporting technique, and the possibility of mixing natural with manufactured gas for maximum economic usefulness in larger centers may justify extending the web of pipe-lines to other parts of the country, plans already announced and others in formation will reveal in the next few years.

Back to the primitive. In swampy land such as this, oxen and mules have proved to be about the best motive power for transporting pipes for the pipe lines

Invalids to or from the Mayo Clinic at Rochester, Minnesota, may ride in comfort in this special car

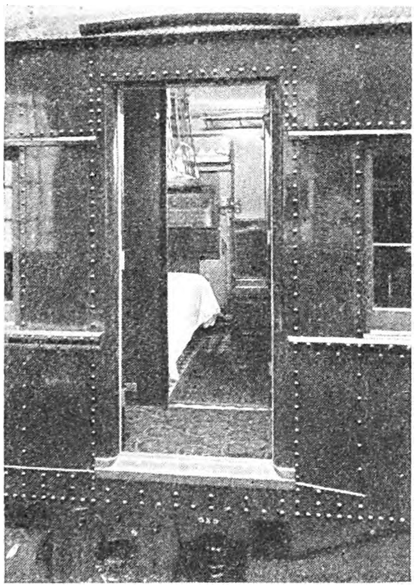
THE SICK MAY RIDE IN PULLMANS

THERE have recently been built, for operation on the Chicago and Northwestern Railway, two Pullman cars specially designed for the comfortable transportation of invalids. These cars will be operated between Chicago and Rochester, Minnesota, home of the famous Mayo Clinic.

Besides the regular platform entrances at the car ends, three doors are placed on one side of each car for the direct entrance of stretchers. These special doorways are 30 inches wide and two of them are so located that a patient on a stretcher may be carried directly into the room he is to occupy; the third provides access to the open-section division of the car. The rooms thus reached are extra wide, and provided with extra wide doors, so that the transfer from stretcher to bed can be made with the least discomfort to the patient.

Each car contains eight open sections, one drawing room, and four rooms; each room having a stationary single bed and an upper berth, as well as folding lavatory arrangements. The upper berth is available for occupancy by an attendant. At the section end of the cars is the lavatory for men, while that for women is at the opposite end.

Particular attention has been given in the construction to eliminating as much as possible the noise of travel. Diaphragms at the car ends are spring-hung from the top, the arrangement greatly reducing the amount of car-end rattle. Further, rubber insets have been placed between car trucks and bodies at points of contact, to absorb shock and further reduce noise. The cars are also equipped with roller bearings.

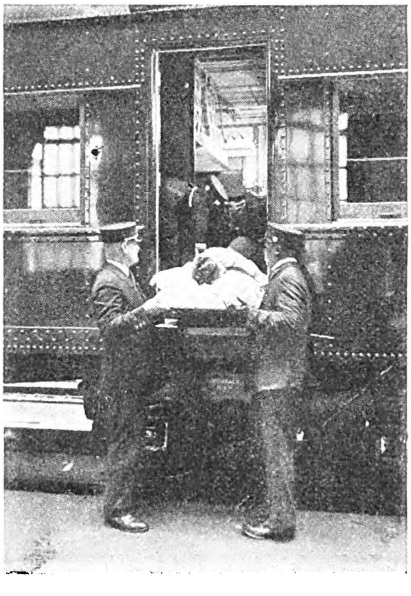


The side door, 30 inches wide, gives access to one of the private rooms

Of invalids who require to travel, the proportion who are entirely bed-ridden is small; nevertheless a considerable number are either bed-ridden or require support in getting about; for these latter a short stretcher, really a canvas seat, 30 inches long, has been devised. This stretcher can be easily handled on entering or leaving the car, because the corridors have been widened for the special purpose of accommodating them. In the ordinary car it has often been necessary to remove a window sash in order to permit a person on a stretcher to be lifted in or out.

The third side-wall door, for patients whose space is in an open section, opens into the crosswise corridor which separates the men's lavatory from the aisle between the sections. Thus only one turn has to be made in carrying the patient in or out, and the use of the platform door and vestibule is avoided.

In a number of other details these cars have been arranged to accommodate this special service; for example, electric heating pads are provided. The cars were designed under the supervision of Dr. Thos. R. Crowder, Director of the Department of Sanitation and Surgery of the Pullman Company. They are appropriately named the *Ephraim McDowell* and the *Joseph Lister*, in honor of two men whose contributions to surgical science have been particularly notable. Ephraim McDowell was not only a country doctor, but a country doctor of pioneering days; he practiced in and about Danville, Kentucky, and there, in 1809, successfully performed the first major abdominal operation ever undertaken, for the removal of an ovarian tumor. There in the backwoods, before the days of anesthesia, unassisted, and with only the crudest of facilities, his boldness and skill combined to bring success in an operation of a type which, now commonplace, has since been the means of saving uncounted lives. Dr. Joseph Lister was the English surgeon who discovered and developed the principles of antisepsis.



The loading and unloading of invalid passengers bound for the Mayo Hospital is rendered easy by the side doors which permit the direct transfer of the patient on a stretcher to the car

THE TECHNICIAN TALKS ABOUT THE TALKIES

By RAYMOND FRANCIS YATES

SINCE the silence of the silent drama has been so effectively—or shall we say devastatingly?—broken, much has been said pro and con concerning this new magic of the movies. It must be confessed that, as measured by the box office receipts, "talkies" have, within the startling space of two years, emerged from the state of an uncertain experiment into that of a bombastic success. How deserved this success has been from a purely artistic or esthetic viewpoint, or how lasting it will be is a matter of some conjecture even at this late stage of development. This much may be said, however. The movie makers have, by sheer luck, struck upon a ready-made, ready-to-use idea that has revitalized the whole industry and captivated a public that is still applauding with enthusiasm.

As large as the success of this new idea has been there are many dissenting votes and much disillusionment on the part of movie goers who want their drama on the hoof, and who demand something more dramatically and emotionally substantial than heated bedroom scenes and voices that sound as though they might be produced when noses are clamped with clothes pins. In short, the talkies have not been universally successful and the possibilities of reaching this point will become more and more remote unless our movie manufacturers see more quickly their folly in attempting to produce pictures to meet the fickle demand rather than a standard of artistic perfection. We have seen and heard the talkies in their unpolished nakedness, and now we want stark realism with a ring of real sincerity back of it.

THE movie manufacturers have still much to learn of technical control of sound recording. To put a bald record of voice or music on the sound track of a film or the wax of a record is one thing. To give that record the expansive breath and verve of life is quite another thing. Even a superficial observer of talkie technique cannot help but lament the obvious absence of realism that is so noticeable in the average production. Contrary to what appears to be the established opinion of the critics, the fault does not lie wholly in the technical limitations of the electrical equipment but partly in its manipulation. To draw an analogy: the movie makers are playing a Stradivarius with the technique of a fiddler at a barn dance. In their frantic effort to please a fickle public and to take advantage of a demand that has swept down upon them with unprecedented fury, they have failed to tap the resources of their equipment.

Situated between the microphone in the set and the recording apparatus there is what is known as a mixing panel. Here the monitor listens-in on all sounds passing over the circuit on their way to the wax and photographic film records. This vigil of the monitor is of vast importance for it is he who regulates the degree and intensity of the sound-laden currents passing over the circuit on their way to the "canning factory." The monitor is lord over all that he hears; he may by a twist of his wrist make a whisper out of a call for help, or he may on the other hand make a cough sound like an eruption of Mt. Vesuvius. It is all in the knobs!

At present it is the monitor who is the weak link in the chain. He is all technician when he should be part technician and part artist. He is interested largely in microamperes and the response curves of audio-frequency transformers when esthetic effects and realism should be uppermost in his mind.

SOME months ago the writer was seated in the studio theater of one of our largest producers, reviewing bits of a musical comedy that had recently been filmed. The novices present talked with a learned air about the "highs" and "lows" of the recording, at the same time being serenely insensible to the appallingly bad job of monitoring that had been done in recording the sound. There was a close-up of a young lady engaged in a normal conversation with a friend. While talking, this young lady turned her back to the audience, but there was no change whatsoever in the intensity of her voice. Here the simple turn of a knob might have added a valuable touch of realism for it is obvious that orientation has a pronounced effect upon the voice. During conversation, turning the head affects the volume of the sound reaching the ear of the listener. A small effect, to be sure, but not small enough to lose every vestige of importance. It is going to be through the painstaking attention to these small effects that the movies will eventually emerge into a state of polished and formal art. The paramount question is,

THE motion picture, and now the motion picture in its talkie form, has become such an integral part of the average person's daily life, that any suggestions for improvement take on a personal interest. In the accompanying article Mr. Yates points out some of the failings of the talkies, and how they may be overcome. His technical background in sound work gives the voice of authority to his statements.—*The Editor.*

"When will the talkies learn to talk?" The answer lies with the technicians whose esthetic sense is usually no keener or more susceptible than that of a coal-wagon driver or an ice-man. It is a far cry from the grid bias of a vacuum tube to the artistic niceties that will eventually put more interest in faithful reproduction.

Some of the efforts of our movie makers to produce realistic effects are painfully amusing to one who has any knowledge of the technical considerations involved. There is a scene on the screen showing a canoe being paddled down a stream in an enormous canyon. The canoe is almost an insignificant speck, a dot in the void of a great spectacle of nature. Strange as it may seem, one hears the dip of the paddle. One who knows the making of the talkies can visualize a stage-hand standing beside a tank of water placed under the microphone and dipping a paddle so that the great American movie audience will be treated to a bit of realism. The whole scene was incongruous enough to make a school boy laugh.

Realism in talkies will not come as an over-night development. It is something that must be fathered, something that must be nursed, something that must grow out of a multitude of unpardonable mistakes. It is something that must be first felt and then learned. However, when one considers that we have had nearly three years of unrestrained talkie making, one is inclined to believe that the perfection of realism has not been as rapid as it should have been. Let us take another example of bad talkie making.

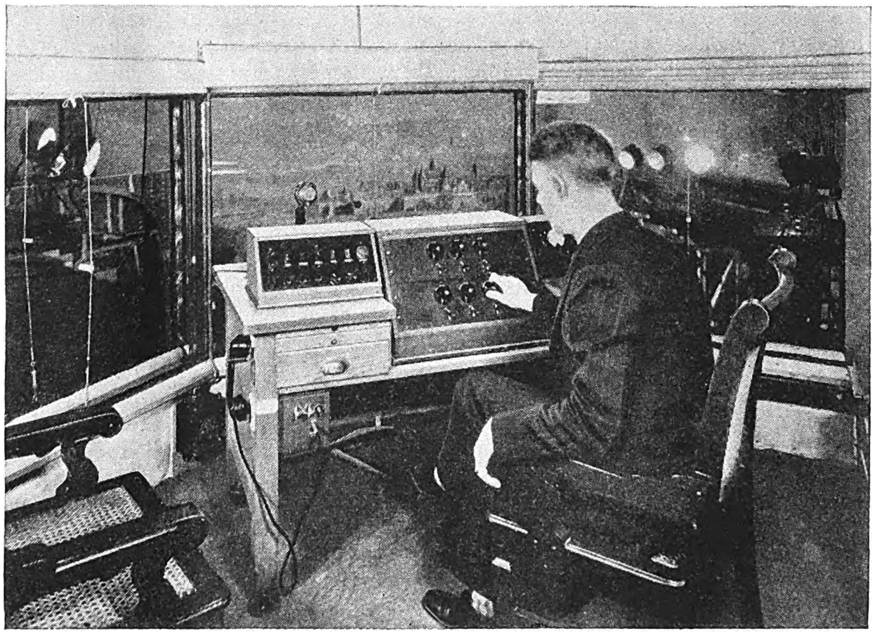
THE scene is a living-room. There is a normal conversation taking place between the occupants. The recording is, on the whole, fairly good. There is a quick flash to the platform of a railroad station. A locomotive with a string of Pullmans rushes into the scene and stops. The effect is terrible. What has happened? The sound produced by the approaching locomotive, a locomotive that one would think almost knocked the tripod from under the camera so closely did it approach, had a volume that was not much greater by comparison than the voices that immediately preceded it in the living-room set. The effect was strikingly incongruous. There was no dramatization at all. The locomotive should have thundered into the scene with a rattle of monstrous iron wheels, with the screaming of brakes and with the glamour and noise that always attends the approach of such gigantic pieces of mechanism. This particular locomotive really almost whispered its way into the scene.

It might be confessed here that the technical equipment in present use is not designed to handle the recording of an approaching locomotive the way the recording of an approaching "he" locomotive should be handled. There is some question as to whether or not this terrific high level of sound intensity could be passed through the amplifying tubes. The question arises: "Why would it not be possible to arrange an automatic switching in of additional amplifying equipment and additional horns so that the whole theater would resound with the thunder of the great iron horse?" It is true that sound amplification, when the sound takes the form of noise, can be amplified to a tremendous extent without the audience becoming at all aware of any distortion. When the sound of an orchestra is recorded the engineer must take care to keep the mould of distortion cut away but when he is recording noise such as the eruption of Mt. Vesuvius or a battle scene, the "sky is the limit." Perhaps we may look forward to the day when locomotives will be locomotives and battle scenes will sound more realistic than Boy Scout Troop No. 125 having their annual outing.

At the present time it is the general practice to place the ear of the "talkies," the microphone, in the center of the set. The technical reasons for this practice have never been made quite clear to the writer. Would it be unreasonable to assume that the microphone, representing as it does the ear of the audience, should be placed at the front of the set in a position bearing the same relation to the performers that the audience bears to the screen? With the microphone assuming this position it would appear that a portion of intelligent monitoring might, to a certain extent at least, be automatically solved.

A still more glowing example of bad manipulation of equipment was recently made obvious when a performer entering an extremely deep set from the back, walked into a close-up as he talked. The monitor had made no effort to fade him in. The sound effects were distinctly displeasing and somewhat incongruous when one realized that a sixty thousand dollar oriental rug adorned the floor and the room was furnished with a carload of expensive trappings fit for kings. There is no expense to which a well-managed studio will not go when it comes to supplying the necessary furniture and equipment and scenery for a major production. It makes one wonder why the smaller details of sound recording are permitted to pass by practically unnoticed.

IT would seem that sound recording is now in the same state of perfection that photography was in 15 years ago. This sorry state of affairs has been brought about by giving the technicians, the sound engineers if you will, too much of a free hand at the studios. Their judgment is in no case tempered with artistic sensitiveness; they cannot see the woods for the technical trees. They are interested in curves and technical precision and they have quite forgotten that technical precision is a far cry from artistic realism. It matters not to the man in the audience whether a tube is biased correctly or whether a resistance deviates one watt or 50 watts, he has come to the theatre to see life lived on the screen, to see an illusion that will be so perfect as to cause him to forget about his daily troubles, his trials and vicissitudes, and the sooner the talkies can deliver this message to him in the true, unvarnished voice of life, the sooner the talkies will be here to stay.



The monitor operator sees all and hears all. He should be part technician and part artist, for by a twist of the wrist he can improve or mar a sound record

A sailing kingbird flying slowly. Primary feathers are outstretched but the false wings forming slots are barely visible

BIRDS HAVE NATURAL SLOTTED WINGS

By RAY P. HOLLAND, Jr.

SLOTTED wings seem to be one of the most recent of the greater aerodynamic developments. It has been in comparatively recent years only that they have been used to any extent at all. As they are used on the airplane, they seem to be one of the man-made devices which have no parallel in nature. There are many such things that appear to have been developed entirely in a scientific laboratory or as the result of continual development of complicated theories. When the result is finally reached and the product is finished, the general opinion is that something entirely new has been made. Then, suddenly, it becomes known that the identical thing that man has worked so hard to attain has existed all the time in a rather simple and surprisingly perfect application in nature.

Slotted wings are an excellent example of this. In nature they are almost as old as flight itself. The earliest flying creatures had no feathers. They flew with a skin web as the supporting surface, as does the bat. With the development of feathers, the primitive slotted wing appeared. That which corresponds to the fingers of our hand became the long, stiff feathers that form the wing-tip of the bird. The thumb developed, on the bat, into a projection to aid it in clinging to walls. On the bird, it became what has been known as the "false wing" or "bastard wing."

The false wing consists of a small group of long, stiff feathers above the leading edge slightly less than half the distance to the wing-tip on most birds. In its normal position, it fits into the conformation of the wing so well that it is not easily seen. When open, it is plainly visible. Being directly in front of the more flexible portion of the wing, it is in a perfect position to direct the airflow over the lateral control surfaces. Thus, in its function it is like the airplane slot.

The manner of operation is slightly different. Naturally, because of mechanical reasons, the bird can not open its slot directly to the front as on the airplane. The means it uses is to move the tips of the slot feathers forward and downward with the joint where the group connects with the wing proper as the pivot. The portion of the wing left exposed by this motion is very well shaped to produce high lift. The feathers of the false wing are disposed so that the cross-sectional shape of the airfoil they form is easily altered. When the slot closes again, the feathers shape perfectly into the wing. It is the ability to change shapes and areas at will that gives the bird such a remarkable control of its flight.

The primary feathers that form the wing-tip of a bird have an aerodynamic action somewhat similar to that performed by the bastard wing. The quill of these feathers is close to the front edge. Each feather is an airfoil in itself. They are arranged so that in overlapping, the leading edge of one feather is above the trailing edge of the feather in front of it. The nearer the end of the wing they extend, the more they diverge, until before the tip is reached, there is space between the individual feathers. The effect is that near the wing-tip there are several airfoils at high angles of attack, one behind the other, the whole group forming one large airfoil. Although not exactly like a multi-slot wing, this arrangement probably has some similar characteristics.

IT is likely that the tips of the primary feathers, which are free to twist over certain limits, place themselves in positions with negative angles of attack when the bird is in certain attitudes. This would form a true multi-slot wing. Mechanical difficulties prevent man from using such a wing, although he understands its action perfectly. This type of wing using numerous slots has been tested in a wind tunnel up to over 40 degrees angle of attack without reaching its "burble" point. The bird probably makes use of the principle in landing and in slow flying. At that time, the tip feathers are spread wide. In rapid climbing, maximum lift is obtained in the same manner.

When high-speed level flight or a dive is desired, the bird's wing-tip moves to the rear in relation to the rest of the wing; folding closes the openings between feathers. In addition to closing the slots, this action furnishes a desirable sweepback. Moving a supporting surface to the rear will move the center of pressure in the same direction and steepen the dive. In extremely rapid dives, birds fold their wings until they are scarcely stubs on the sides of the body. In this means of airfoil modification, natural flight has one of its greatest advantages over artificial flight.

The very shape of the wing-tip feathers is strong evidence that they act as individual airfoils. They are flat and of practically uniform chord out to the point where they are spread wide enough to cause a space between them when the wing is spread. At that point there is a sudden tapering of the plan form. The part of the feather in front of the quill narrows down almost to nothing. The feather becomes an efficient airfoil instead of only a component in a arrangement that makes up one larg surface. The cross-sectional shape f these feathers is usually similar to hat used on our racing planes, but eve thinner. It is so thin, in fact, that it ould not be practicable to construct a airplane wing using the same proport ns.

As an example of a bird ich uses its slotted wings to great adv tage, let us consider the wild duck. C tain species of them migrate from as ar north as Alaska in the summer and uthward to the Gulf of Mexico in t winter. When not disturbed, they pr r not to fly, unless they have a certa destination. In their flight to that tination, they travel in a straight line a high speed. When disturbed, the must be able to climb almost vertical for their protection. Also, they posses marked ability to change direction d speed suddenly when they see som ing that arouses their suspicion.

Suppose that an order should be received in an aircraft factory for a ship of very high wing-loading, the nearest thing possible to a racing plane, that would have a low landing speed, an ability to stunt, extremely good climb, and also be capable of long-range non-stop flights. It would be absurd to try to fill all the specifications in a single ship. Any one of the requirements could be fulfilled in a specialized job for that purpose, but no individual plane could possess all the qualities necessary. Nevertheless, a duck can do all those things.

After flying all night at a high altitude, the duck reduces its wing area to almost nothing, shifts its center of pressure to the rear, and begins a long bullet-like dive to just above the surface of the water. At that point, it increases its wing area and resistance at the same time. As its speed diminishes, the false wing moves forward from its position to form the slot. It maintains perfect lateral control up to the point when it becomes practically motionless in the air only a few inches over the water. Then, with a few flaps of the wings, it lets itself down easily. If it is disturbed, it springs from the water with amazing alacrity. A rapid and steep climb is maintained until the bird is out of danger. During this climb, the slots are continually open. They are, more than any other one thing, responsible for this performance. They increase the lift and prevent "burbling" in the attitude necessary for the climb.

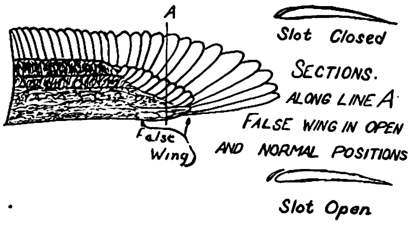
DIFFERENT birds, depending on the degree to which they use them, have slotted wings developed to different degrees. Generally, the false wing is comparatively small on gliding birds. They are slow fliers that employ extremely efficient airfoils. Birds such as the albatross derive their efficiency from a supporting surface of very high aspect ratio. Their light wing-loading provides a sufficiently slow landing speed for them. Great climbing speed is unnecessary because they fly over level stretches of water with only slight changes in elevation. Their continuous gliding is made possible by the rising currents of air caused by the swells of the sea. Birds utilize these slopes of water in exactly the same manner that a sailplane uses a long gradual hillside.

Those birds which have a high-speed flapping flight have the slots developed to the greatest extent. They are birds of very high wing-loading. High-speed wing action is necessary in order to maintain flight. Nevertheless, a remarkable rate of climb and a reasonably slow landing speed can be produced. Quail, grouse, and pheasants are birds of this type. Examination shows that these birds have abnormally large bastard wings.

I have noticed that the position of the slot varies on birds of different sizes. To illustrate this, I will compare the Hutchin's goose, which weighs about eight pounds, to a representative small bird. The center of the group of feathers, on the goose, that constitutes the bastard wing, is approximately 58 percent of the distance from the body to the tip of the wing. On the smaller bird, it is only 37 percent of the distance out. The smaller bird's false wing occupies slightly over 20 percent of the leading edge, while that on the goose occupies only 17 percent of its leading edge.

HOWEVER, this latter comparison creates the wrong impression because the goose is a bird of high aspect ratio while the other is not. The slotted wing area of the goose is much larger in comparison to the entire wing area than is the case on the other bird. Its wing-loading is considerably greater also. The manner of flight, in the same way that it affects the size, is likely to have a direct bearing on the position of the false wing.

On the ruffed grouse, a bird of heavy wing-loading that flies with an extremely rapid wing action, the slot feathers are very close to 50 percent of the distance to the tip. On birds of light wing-loading it is usually less than half way out. These observations indicate that the bastard wing, viewed from a standpoint of size and position only, has a direct relation to the size and flying characteristics of the bird, and must be a part of its control system, and not merely a useless appendage.



Goose wing showing similarity to airplane slotted wing arrangement

If you would like to see a practical example of the actual means the bird uses to open his slotted wings, it is only necessary to obtain a bird's wing to experiment with. This should be easy, for there are many species of detrimental birds, such as the hawk or crow, that may be killed at any season. The wing of the bird, cut from the body, is all that is needed. There is a tendon just in front of the wing bone. As this is pulled the wing starts to unfold. Everything goes on normally with the false wing in its original position until the maximum wing area is reached. In landing, the bird would employ this position of its wing in order to have the lightest wing-loading, and consequently the slowest landing speed. It is also in landing that it makes the greatest use of the slotted wing. It is, therefore, logical that the action of the false wing should be governed by the tendon that holds the wing outstretched.

By pulling with slightly more force on the same tendon, the false wing will move forward and downward into its correct position to act as a slotted wing. When actually seen operating in this manner the function of the so-called bastard wing is very evident.

ACTUAL photographs showing the slots open on flying birds form the only more convincing evidence I know of. It is difficult actually to watch birds and see the system in operation, even with binoculars. The opening is slight and there is only a short period of time during which to observe it. It may be seen after much effort but not distinctly enough to be a proof. However, to take a wing in your hand and actually make the slot open, will make even the most stubborn doubter stand convinced.

•

THE SCIENTIFIC AMERICAN DIGEST

Conducted by F. D. McHUGH

NOW YOU CAN BUY INSECTS FOR 10 DOLLARS A MILLION

TEN dollars a million for insects! Who'll buy? The average stung, bitten, and be-itched picnicker or camper may ask wearily why anybody should want to buy a million insects at that price when you get more than a million for nothing every time you show your nose out of doors.

Recently developed safe, fireless lamp for flashlight photography

But the insects that are worth 10 dollars a million are cheap at the price, for they prey on the eggs of other insects, thereby preventing the pests from ever seeing the light. They are the almost microscopic wasps known as *Trichogramma*, which are reared in captivity by Stanley E. Flanders, entomologist of the Citrus Experiment Station at Riverside, California. Mr. Flanders has been at this work for some time now, and has improved his rearing methods to a point where the tiny parasites can be produced at a thousand for a cent. They are shipped out in great numbers to orchardists, who release them to assist in their endless warfare on fruit-spoiling insect pests.—*Science Service.*

NEW PHOTO FLASH LAMP

A FIRELESS, smokeless, odorless, and noiseless photographic flash lamp has been developed by the incandescent lamp department of the General Electric Company, Cleveland. The flash is confined entirely within a bulb, with resulting advantages that are expected to revolutionize flashlight photography. Requiring only one-hundredth of a second to act, and being without hazard, it will make possible the taking of flashlight photographs in places heretofore practically impossible to "shoot," such as in trains, airships, and theaters, under water, and by insurance companies requiring night photographs under all weather conditions.

The lamp consists of a clear bulb of standard design, with the flashlight filament coated with a special preparation, and with a quantity of very thin aluminum foil in crumpled sheet form within the bulb. The bulb is oxygen-filled.

When the circuit is closed the filament is lighted and this, in turn, lights the foil. The lamp operates on any 115-volt house supply, or with dry, storage, or flashlight batteries. A new lamp is needed for each flash. The lamp is most efficient when used with suitable reflector equipment.

NEW PROCESS FOR CARBON BLACK MANUFACTURE YIELDS HYDROGEN

THE production of carbon black from natural gas has been, heretofore, a wasteful process, but experiments carried out by the United States Bureau of Mines give promise of an increased yield of more than 400 percent.

The old method, and the one in widest use, consisted of burning natural gases incompletely and collecting the unburned carbon on cold metal surfaces when the gases passed off. Sometimes the carbon black was collected by filtering the gases through cloth.

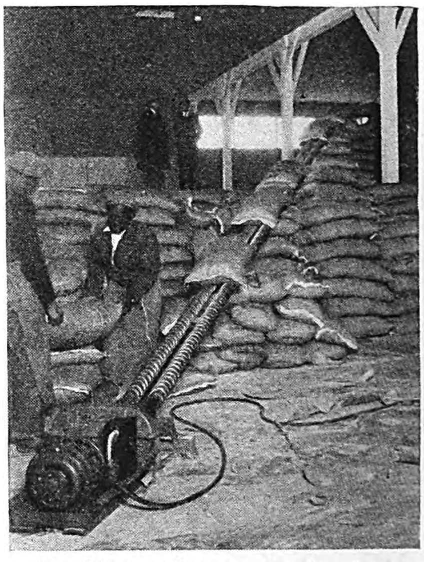
The new method calls for the passing of the gases through ignited coke. The coke is fanned to great heat by subjecting it to a forced air draft, after which the natural gas is passed through it and cracked.

An advantage to be gained by the new process is that, in addition to the carbon black, hydrogen may be recovered and used in some localities for the synthesis of motor fuel and the manufacture of ammonia and other products.—*A. E. B.*

DOUBLE-SPIRAL CONVEYOR

A NEW portable, flexible, power-driven, elevating and tiering conveyor has just been introduced and has already found many useful applications in a wide range of industries.

The TwinVeyor, as this new apparatus is called, uses a new principle: two external spiral tubes are turned toward each other by a power head. Anything placed on the conveyor travels forward rapidly, perfectly balanced. It is used for handling raw materials and finished products in bags, bales, and bundles. The equipment finds other applications handling crates and boxes, and experiments are being made handling the finished product itself, without packaging, where its shape and size permit the spirals to get hold of it. It carries bagged sugar up a 30 percent grade at the rate of 90 feet per minute, handling 1800 bags per hour.



Double spiral conveyor for bags and bales. It is motor operated

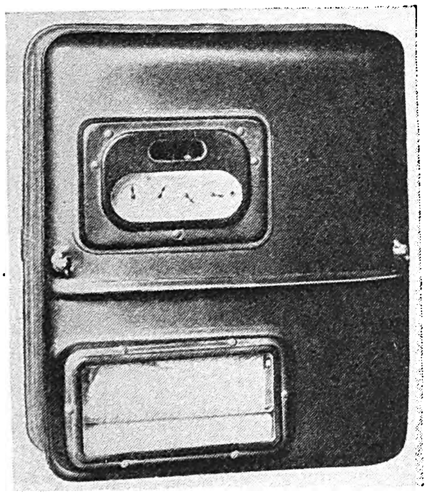
A standard unit consists of six eight-foot dual sections and a power head which draws current from any power line. Each section joins to the assembly with an automatic lock. It is easily shifted about by one man and the entire 50-foot line can be assembled or disassembled in six minutes. Flexibility is secured by the ability of any joint to take a 15 degree angle horizontally, 15 degrees up or 10 degrees down.

A hurdle section permits any number of TwinVeyor 50-foot units to be hooked together, forming a continuous line of any desired length. The traveling load hurdles each power head in the line. Right and left spiral chutes are provided for shunting the load from one TwinVeyor line to another without manual handling, thus making right-angle turns simple.

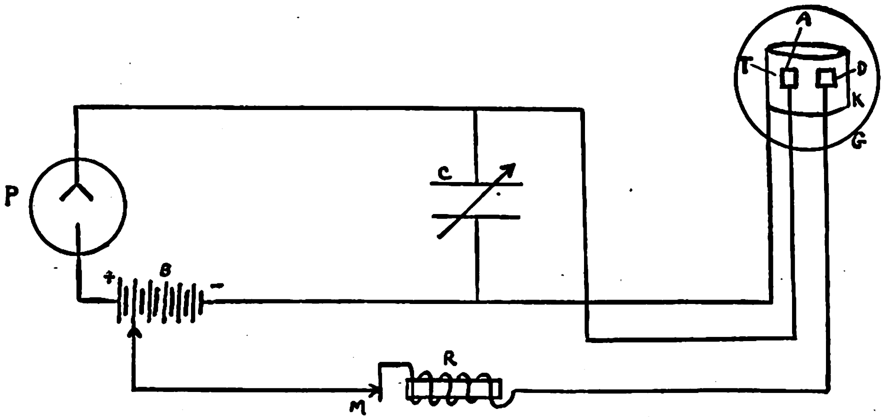
MEASURING ULTRA-VIOLET RAYS

THE element of danger in the indiscriminate use of the ultra-violet ray has had to do with the dosage, the amount of exposure, the proper measuring of ultra-violet radiation for the purpose at hand. It has heretofore been a difficult task to measure this amount exactly, but now there is an ingenious device for the purpose, an ultra-violet ray meter that records the amount of ultra-violet rays coming one's way as accurately as an electric house meter gives the amount of electricity one is consuming in the home.

This indicator operates from dry cells within it. Its essential element, the "eye" of the instrument, is a photo-electric cell which was developed by Dr. H. C. Rentschler of the Westinghouse Lamp Company. The cell in this case is sensitive only to those light rays supposed to have therapeutic value or other effect on vitality—rays .0029 to .0031 millimeters in wavelength. The cell itself is the result of research findings that: (1) By a proper selection of the active material, a cell may be obtained that will not respond to light of longer wavelength than that desired; and: (2) By use of proper light filters it will not respond to light of shorter wavelength than that suitable for the purpose. (A cell of uranium metal and Corex D glass, for example, responds only to that band of light used in prevention and cure of rickets.)



Graphic meter for recording the quantity of ultra-violet on a chart



The circuit of the instruments used in the ultra-violet ray meter

When the rays strike the cell of the meter, a certain amount of current passes through it, proportional to the intensity of the rays, and charges a condenser which, when fully charged, trips a counter. The operation is then repeated, each impulse measuring a definite quantity, irrespective of the light intensity. Since the unit of measurement has at present no name, the value taken is arbitrary. Over a given period of time the number of impulses per minute, each accompanied by a "click," thus indicates intensity, while the total number of impulses indicates quantity.

The principle on which the meter operates is as follows, referring to the diagram: A battery B charges condenser C at a rate determined by photo-electric cell P when light falls upon the cathode. Glow tube G has metal cylinder K for cathode and a primary anode A and main anode D. A small gap exists between A and cathode at T. When C is charged to a potential such that a discharge takes place between A and K, the cathode resistance of the glow tube is broken down and current flows between D and K. This operates the relay R, registers the count, and opens the main circuit M. The condenser is discharged simultaneously. The operation is then repeated. The total quantity of light falling on P is proportional to the total number of discharges registered.

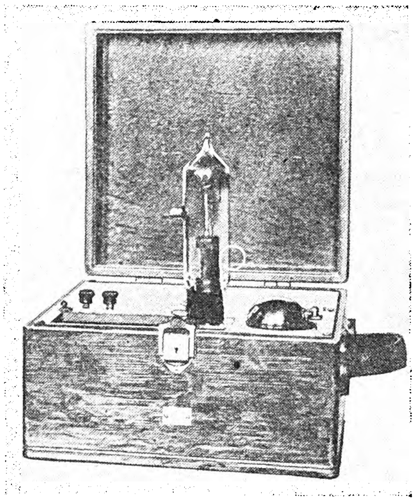
WOOD ALCOHOL

WITHIN recent years it has become possible to produce synthetically the wood alcohol that was formerly prepared only by destructive distillation of wood. The substance is now manufactured from water-gas and hydrogen at a cost which makes it possible to produce large quantities at a low price. Modern industry is, therefore, attempting to introduce the substance for a large variety of purposes, including its use as an anti-freeze mixture in automobile radiators. It is also used in the manufacture of quick-drying shellacs and varnishes. It has long been known that wood alcohol is a dangerous poison with cumulative effects. When taken frequently in small doses, it produces blindness; in large doses, it causes death. The added danger from this product is in the fact that the repeated inhalation as well as the drinking of very small doses of the poison may produce the most serious results.

If this substance is to be used as an anti-freeze mixture in the coming winter, employees of garages who will inhale large amounts of it from overheated radiators are likely to suffer serious injury as a result.

Cases have already been reported in which women and children who have used quick-drying shellacs or varnishes, made with methanol, in closed rooms have suffered harm as a result. In the great spray process used in automobile factories, the spraying is done under hoods and employees wear masks, so that they are protected against the hazard.

As is usual in modern industry, the name of the product has been concealed by the bestowing of fanciful names and the average person does not recognize under the name *methanol* or some other fanciful title the old, old hazardous wood alcohol.—*M. F.*



Ultra-violet indicating meter which uses a special photo-electric cell

FEATS OF SHORT WAVES

RADIO waves which will do the family cooking, provide wireless illumination for homes, alleviate pain, and cure disease are the goal of new investigations into the possibilities of the short-wave high-power vacuum tube, according to Dr. Willis R. Whitney, director of the General Electric Research Laboratories, in a research narrative issued by the Engineering Foundation.

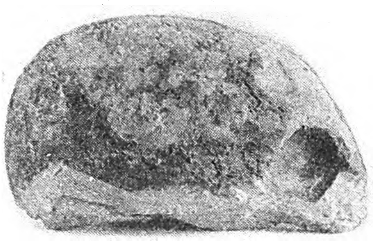
Control of this power for practical uses will immediately open up lines of advance in industry and therapeutics hitherto closed to science, it is stated. Simplified mechanisms and a reduction in the cost of producing large volumes of radio energy are the problems now facing solution.

Radio cooking has already been demonstrated in tests with the new tube.

"A wire was suspended over a table,"

Dr. Whitney states, "at a distance of a few feet from the radiating aerial, which was a copper bar about 10 feet long. A sausage in a glass container suspended from the end of the wire was soon cooked. Likewise an egg was 'fried' in this container, and an apple spitted on the end of the wire was thoroughly baked in a short time. .

"With suitable changes of utensils, cookies were baked and water boiled. There were no flames or other visible evidences of heat accompanying the cooking. The vacuum tube from which this weird power emanated was only two feet long and five inches in diameter.



Robert P. Robinson of the Skelly Oil Company, found this stone at San Angelo, Texas. Its resemblance to a human skull is striking, but since it came from rocks of the early cretaceous period, thus making it something like 115,000,000 years old, scientists are not inclined to take its human origin at all seriously

"As yet the high-power short-wave vacuum tubes are being used for experimental purposes only. To bring them into practical usefulness at reasonable cost and discover their many possibilities for service to mankind is now our task."

BLOOD PRESSURE

THE blood pressure of human beings is measured by putting an elastic cuff around the arm, inflating it with air, and then listening to determine the points at which the sound of the blood in the vessels is extinguished and the point at which it again appears when the pressure of the cuff is released. This simple test has been of tremendous importance, particularly in examinations for life insurance. A normal blood pressure is recognized as being approximately 120 millimeters of mercury. Insurance companies insure persons with pressures ranging from 100 to 140.

In order to make some more exact determinations regarding blood pressure of a considerable group under controlled conditions, Drs. W. C. Alvarez and L. L. Stanley took the blood pressure of all of the prisoners in the San Quentin prison in California. They are inclined to believe that there is a normal blood pressure for each person; that if a person has a high blood pressure at 20 years of age, he is likely to have a high pressure at 40. The lower limit of normal pressure they found to be 90 millimeters of mercury and the upper limit 140. They found the normal pressure about 115, which is lower than the figure usually found for men out in the world. The reason for this they consider to be the fact that the prisoners are not fatigued and worried by the struggle to make a living. They did not find that alcohol affected the blood pressure, but tobacco appears to raise it about 4 millimeters.

Men who have been convicted of murder in the first degree showed a blood pressure slightly higher than that of other prisoners of the same age. They found that the prison guards had a pressure considerably higher than those of prisoners, which they consider to be due particularly to overweight, and also to the fact that the guards were applying for positions at the time when the pressures were taken and that many of them were anxious for fear they might be rejected.—*M. F.*

POTATO RUBBER

THE Firestone Tire and Rubber Company is experimenting on the commercial value of a new variety of rubber with potato starch as the base. The synthetic product contains no latex or plantation rubber. It is made by mixing the starch with chemicals which coagulate it into a gum-like substance differing from rubber only in that it is less elastic.—*Barron's.*

REFRIGERANTS FROM THE TROPICS

"YOUNG as we are," says Dr. H. E. Howe, editor of *Industrial and Engineering Chemistry*, "we can remember the days when sailing vessels carried cargoes of natural ice from Maine to Cuba, and we believe even as far as Calcutta. How times have changed!

"There is now en route to New York from Mexico one of three vessels, each of which has been equipped with a compartment insulated against heat exchange by 12 inches of cork board to bring solid carbon dioxide to the metropolis for refrigerating purposes. One of the petroleum companies in drilling for oil struck a supply of carbon dioxide which rushed to the surface at a pressure of 1000 pounds.

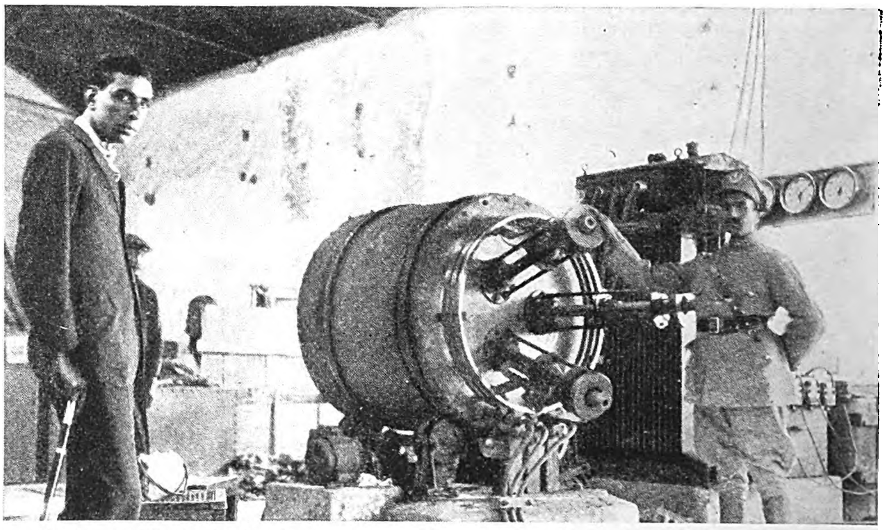
"It is much too early to discuss the economics of this venture. Inasmuch as the solidified gas must be cleaned of its impurities before it can be re-made into commercially pure solid carbon dioxide, it is doubtful whether the natural high pressure will be of much advantage, and undoubtedly there have been some nice technical difficulties in the purification of this particular supply of gas. We have yet to learn, too, with what efficiency and what percentage of loss the solid gas has been stowed in the hold, transported, unloaded, and distributed. These are technical details concerning which no information has so far been made available. However, the whole venture is intriguing. The mere thought of preparing a refrigerant in the tropics for shipment into the temperate zone is so complete a reversal of the old established practice as to afford another example of how chemistry is helping to remake the world."—*A. E. B.*

NEW INSECTICIDE PRODUCED BY "CUBE ROOTS"

IT used to be a favorite wheeze at college to suggest to the room-mate who had prematurely squandered his allowance that he write home for funds with which to buy a cosine for use in mathematics class. We used to assume that Dad either had never been exposed to trigonometry or had forgotten that a cosine was merely a mathematical function of an angle and that he would "enclose check" rather than admit ignorance. We were forcibly reminded of that ancient practice by a recent statement in a publication of the staid United States Bureau of Agriculture, when we noticed the sentence "cube roots are not yet available commercially."

We still think Dr. R. C. Roark, of that department, had his tongue in his cheek as he wrote that sentence, but further investigation revealed the fact that "cube" is a South American plant and like most other plants, it has roots. (The plant's name, incidentally, is pronounced koo-bay.)

In the course of this reading, we learned further that the cube plant has been found to contain a substance called rotenone which has been found to be an excellent insecticide. The Department is therefore urging the Malay States to grow rotenone-bearing plants on a commercial scale for



Even turbulent Afghanistan, where kings are made and unmade overnight, must have coins. Here is shown the electrical smelting machine, imported from America, which has just been installed in the mint at Kabul, the capital. Beside it stand an army officer and a modern young Afghan "intellectual"

American trade. This new insecticide is found in quantities up to 7 percent in the root of the South American cube plant, up to 5.5 percent in derris roots, and to a lesser extent in three other plants. The cube plant now grows in a part of South America where the climate is similar to that of the Malay States and surrounding countries.

Tests by the Department of Agriculture indicate that rotenone is highly poisonous to both sucking and chewing insects. In tests conducted privately, rotenone was fed to dogs, cats, sheep, and chickens in quantities up to 1 grain per pound of body weight and no injury was noticeable.—*A. E. B.*

KETOGENIC DIET IN EPILEPSY

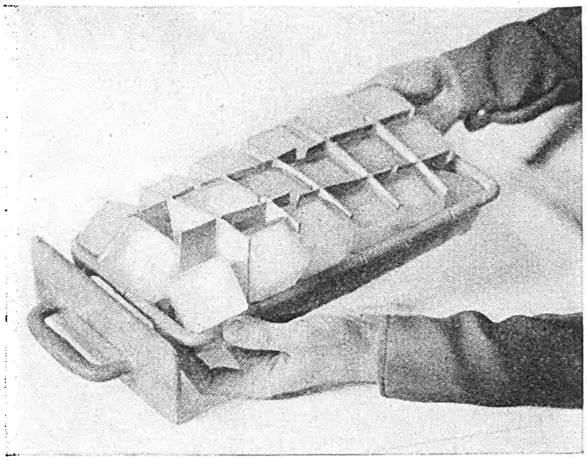
IN 1921 it was suggested that children with epilepsy might have the number of their attacks greatly reduced by providing them with a diet low in protein and containing large amounts of fat as compared with the amount of sugar taken into the body. This is called a ketogenic diet, because it tends to produce an excessive amount of ketones and their derivatives in the blood and in the excretions. The diet must be carefully watched, since an excessive amount of this substance produces serious symptoms.

Recently, Drs. Henry F. Helmholz and H. M. Keith have recorded the results of this diet on 272 children who had suffered with epileptic attacks. Two hundred forty-three children with epilepsy of unknown origin, in that the attacks could not be related to any disease or surgical disturbance, were treated by this diet. One hundred seventy-one of these children cooperated fully. One hundred forty-one children had been on the diet more than a year and 30 had been treated less than a year. Of the 141 patients treated for more than one year, 43 patients had remained free from epileptic attacks from one to seven years, and 32 others had shown definite improvement, as evidenced by the decided improvement in the number and severity of the attacks and by improvement in their general demeanor.

It has been argued by some observers that dehydration of the body is an important factor in the lessening of the convulsions. The investigators admit that this plays a part, but do not believe that it is the only factor.

Apparently 30 percent of the patients with epilepsy of unknown origin are freed from convulsive seizures by the use of this diet and, under completely controlled conditions, as many as 37 percent may be relieved of their disturbance. It is, of course, impossible to keep such children in hospitals over many years, and it becomes necessary for parents in the home to learn how to handle the diet and to take care of the child properly.—*M. F.*

Ordinary ice cube trays of automatic refrigerators are unsatisfactory because it is difficult to remove one or two cubes without emptying the tray entirely. A flip of the finger, however, is all that is necessary to remove just the number wanted from this new tray developed by the Frigidaire Corporation. It is made of strong rubber on a rigid steel rod frame



CHEMICAL PARADOX LEADS TO BETTER INSULATED WIRE

RUBBER is a non-conductor of electricity. Carbon black is a conductor. Therefore, it would appear natural that the admixture of carbon black in rubber would increase the latter's conductivity. In fact, this has been generally assumed to be the case until W. B. Wiegand and C. R. Boggs, in a recent issue of *Industrial and Engineering Chemistry* disclosed experimental evidence to the contrary. As a matter of fact, up to about 10 percent, by weight, of properly made and dried carbon black may be added to each 100 parts of rubber hydrocarbon present in rubber insulating compounds with marked improvement in dielectric strength, resistivity, and power factor, and without serious increase in dielectric constant of the rubber insulation.

The exact amount of carbon black required depends somewhat on which electrical property is to be brought to its maximum value.

This discovery is of importance to the makers of insulated wire who use a rubber covering next to the metal. In fact, these results would seem to render advisable the rewriting of many specifications dealing with rubber insulating compounds, and thus make it possible to apply the well-known beneficial effects of carbon black compounding—improved toughness, density, wearing resistance, imperviousness to light, tear resistance, and so forth—to the electrical insulation field, from which it has hitherto been barred.—*A. E. B.*

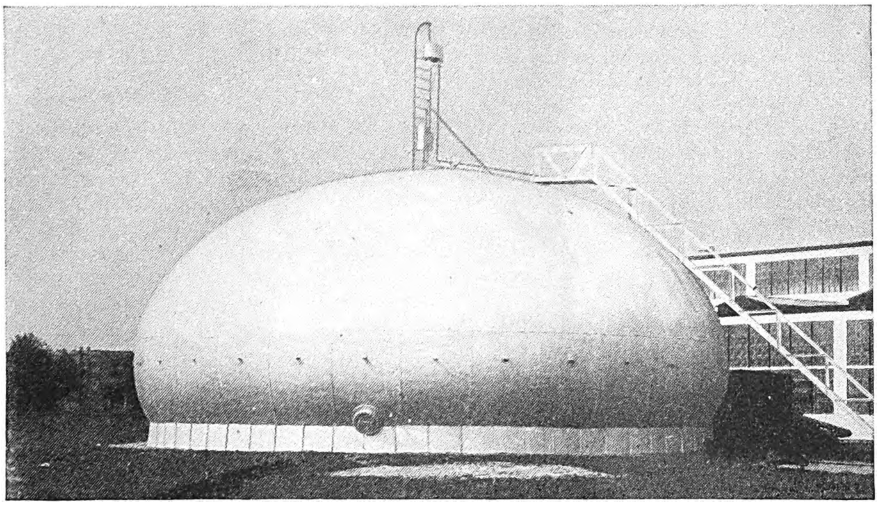
NEW OIL TANK HAS UNIQUE SHAPE

IF you were to visit certain oil company properties in Texas you would see unusual steel structures which have the appearance of giant mushrooms breaking through the ground. They are a new type of storage tank designed by the Chicago Bridge and Iron Works.

The Hortonspheroid, as this unusual shaped tank is called, is used to store high-test gasoline and other volatile oils. Such liquids are placed in the tank and the tank closed tight to prevent evaporation loss taking place.

It is possible to close the Hortonspheroid tight because it is designed to withstand a certain pressure, usually 10 or 15 pounds per square inch. As the temperature rises, the pressure increases but no vapor escapes. Each installation is, of course, equipped with a safety valve.

But why the unusual shape? It is simply the shape which a flexible container would take if filled with liquid and subjected to a few pounds pressure. It is the most natural shape for such conditions and, by the way, the most economical one, as all of the metal used in its construction is used effectively.



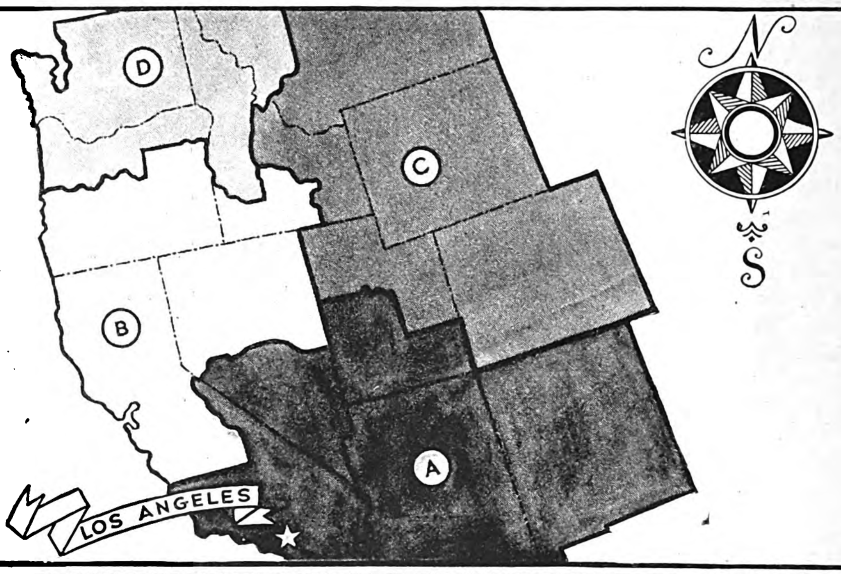
Looking like a huge drop of water on some oily surface, this Hortonspheroid holding 10,000 barrels of oil, was built for experimental purposes at Chicago

SWORD SWALLOWERS

THE sword swallower is able to pass a long knife down his throat by developing a special agility in the movement and by developing also the ability to breathe by movements of the ribs without moving the diaphragm. That fact was recently determined by three French physicians who subjected two sword swallowers to a

Western Market

12 Million People



— served most economically from Los Angeles County

There is a distinct freight advantage in serving the Western Market of 12,000,000 population from Los Angeles County... its largest metropolitan center.

Zone A —Population 3,982,582... Local market immediately tributary to and including Los Angeles County.

Zone B —Population 3,002,753... Local market.

Zone C —Population 2,239,483... Parity in freight rates enjoyed by Los Angeles County.

Zone D —Population 2,598,129... Served from Los Angeles Harbor by regular steamship transportation, at low freight rates.

Truck haul delivery is made direct by manufacturers in Los Angeles County to three-fourths of the 4,000,000 people in Zone A... at a freight rate advantage so large as to more than offset slight rate differentials via water route to Zone D.

It will be obvious to the manufacturer who wishes to serve the entire Western Market that he can do so at a great saving by locating his plant in Los Angeles County.

ANDREW WELLS ROBERTSON

A HIGH SCHOOL principal whose vision saw beyond the confines of school walls and whose understanding of men, fairness, and canny Scot's industriousness have carried him to the high position of Chairman of the Board of the Westinghouse Electric and Manufacturing Company—that, in brief, is the biography of Mr. Robertson. Like many other leaders in American industry, Mr. Robertson's family background is modest. His father, a native of Scotland residing in Panama, New York, was a stonemason by trade. He died when young Andrew was but three years of age but this did not prevent Andrew from getting an education. He was graduated from Allegheny College in 1906 and was principal of a high school for a time. He studied law while conducting a private school for boys and was graduated from the University of Pittsburgh in 1910 with the degree of LL.B. Admitted to the bar, he joined a Pittsburgh law firm, practiced privately for a time, and later became trust officer for a large Pittsburgh firm and attorney for another. By 1918, he had become general attorney for the Philadelphia Company, was made vice-president in 1923, and president in 1926. In 1929, he attained his present position with the Westinghouse company. He is a trustee of his two alma maters, a director of many large corporations and associations, and a member of New York and Pittsburgh clubs. Being an able speaker, he is much in demand on public occasions but has never been attracted to politics—he has been too busy for that.

THE TREE BARK OF A HUNDRED USES

By BURTON DAVIS

WHEN the dry sirocco sweeps up off the Mediterranean and blows its hot breath on the Latin lands that border it to the north, there is one tree that remains gayly green. When the simoons twist north from the parched sands of the Sahara and whirl across Algeria, Tunis, and Morocco, one evergreen oak flourishes. That tree is protected by nature with a thick layer of the finest natural insulation in the world: you know it as cork.

All woody plants have a coating of cork, but this one sort of oak has more than any other. Certain elms and birches elsewhere in the world have outer bark that resembles it, but theirs is comparatively useless to man. The outer bark of *Quercus suber* and its almost identical cousin, *Quercus occidentalis*, known as the cork oaks, is in many ways unique in nature and invaluable in human industry. Nothing natural nor artificial has yet been produced to compare with it, for the *Quercus* bark has seven properties: resistance to the passage of moisture and liquids, buoyancy and light weight, resilience and compressibility, ability to absorb sound and vibration, strong resistance to progressive deterioration, low conductivity of heat, and an uncommonly high coefficient of friction.

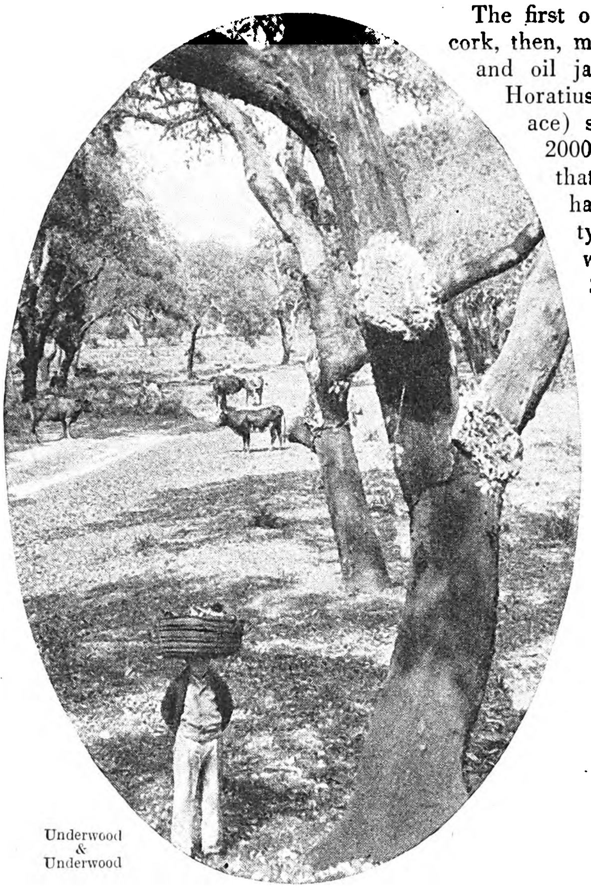
Through at least 2300 years, these properties have successively been discovered and utilized by man. Yet, although cork now has more than 150 distinct uses in the complicated apparatus of civilization, little is known about the physiological, physical, and chemical properties of the odd material.

ALL the literature on the subject of cork, including reports of previous research, could be carried in a small brief case. The men who have handled cork throughout the ages never bothered to find out much about it. A dozen chemists and botanists had worked on the problem of explaining how it grew and of what it was made up, but from 1787 to about 1927, had chiefly developed theories that were later discarded.

There was no accurate information on the number of cork trees in the world and how much cork bark they could supply. Man was using a natural resource and might reach the limit of its supply. Reforestation of cork oak had been largely left to nature and rare private enterprise. Culture of the cork oak was not fully understood. All this had to be studied so that provisions could be made against the future.

And that was what the American cork manufacturers set out to do less than a year ago. Since then another factor has loomed up. Apparently we are about to enter another ice age, this time in food distribution, for huge plants are being built for the quick freezing of meats, fish, vegetables, and fruits to be retailed in packaged form, hard frozen, and kept at sub-zero temperatures. Such low temperatures in freezing plants, refrigerator cars and trucks, storage cases, and household iceboxes will demand cork-board in huge quantities.

Cork, therefore, has rather suddenly become an object of keen industrial interest. The factories called in the research doctors and set them to work to find out how cork is put together, of what substances, and, in exhaustive detail, what its physical and chemical properties and peculiarities are beyond the known and obvious ones. Cork was such a mystery that there was no predicting what they might uncover. To develop a satisfactory substitute for cork is one of the things the scientists hope to do, although at present that



Underwood & Underwood

Cork oaks partially stripped of their valuable bark in a scattered grove at Almorasma, Spain

seems to be a hopeless, impossible task.

In the research and testing laboratories of a large cork company at Lancaster, Pennsylvania, only lately a photomicrographer took the first picture of the individual cork cell. The research, by scientists attached to the company, that led up to the taking of this picture—as well as the picture itself which is reproduced on page 347—showed that the cell has the geometric form known as tetrakaidecahedral.

This difficult word is from the Greek and means "having 14 faces." Lord Kelvin, years ago, found that units of 14 faces solved the problem of dividing all space, without interstices, into uniform bodies of minimal surface. In 1928, Dr. Frederic T. Lewis, of the Harvard Medical School, conducting independent research into cell structure, demonstrated that cork cells are tetrakaidecahedrons, each making contact with an average of 14 others.

EVEN though there are minute interstices between cork cells, these are filled with resin that is impervious to water and most liquids. Obviously a substance, the cells of which fit so snugly, is going to baffle the passage of any fluid which is unable to eat its way through. Thus the word for cork is the word for stopper, also, in most languages—a "stopper" is a "cork."

The first of the seven properties of cork, then, made the stopping of wine and oil jars one of its first uses. Horatius Quintus Flaccus (Horace) spoke of that in Ode III, 2000 years ago. Earlier than that, doubtless, the ancients had used the second property: buoyancy and light weight. Pausanias (not the Spartan admiral, but the traveler and geographer of the 2nd Century, A.D.) recorded that cork bark was used for anchor boards and on fish nets. Since each cork cell is more than half filled with air, the mass is buoyant. Its specific gravity is between .15 and .20, making it one of the lightest of solid substances.

The cell walls of cork are of tough, highly elastic material—much more so even than rubber—hence its resilience and compressibility. At Lancaster a one-inch cube of natural cork was recently put under pressure of 14,000 pounds to the square inch. The sidewise spread under that load was only a quarter of an inch. Released, the cork in a few hours regained between 90 and 95 percent of its original height, while the horizontal edges of the cube returned to exactly one inch. The secret of cork's unique behavior appears to be that only the air in the cells is compressed, hence the lack of side spread and the unequalled regain. Corks jammed in champagne bottles for 10 years will regain three-quarters of their original volume shortly after being withdrawn from the bottle.

Sure-footed burros, top-heavy with huge loads, transport cork in the mountainous sections

Since dead air, in finely divided spaces, is, next to a vacuum, the best insulator known and the poorest conductor of sound and vibration, the fourth and sixth properties of cork are easily explained.

What will keep out heat will, in the popular phrase, "keep out cold"—which means it will keep heat *in*. Hence the use of cork-board insulation, which threatens to outstrip every other use of the cork in a few years, not only to insulate refrigeration units but also to insulate buildings against the winter's cold and the summer's heat. That last-mentioned use may have been the first to which cork bark was put, for the peasants all over the cork oak country still roof and wall their huts with slabs of the crude cork.

THE known chemical inertness—except to a few acids and strong alkalies—of the walls of the cork cell and the intervening resin explains cork's uncommon resistance to deterioration.

The fourth and seventh properties in the list have been the last to be utilized. Cork has only lately come into general use to absorb sound and act as a corrector of acoustics in echo-haunted halls and rooms. The first use in this respect was of cork tile as flooring for libraries and hospital halls. Now whole auditoriums are lined with a fine-grained cork-board. Radio broadcasting and sound film studios are using cork to exclude exterior noises, reduce interior sound and vibration, and break up echoes. Lastly, cork, long applied to reduce vibration and clatter in machinery of a hundred kinds, is now being used in slab form to insulate machines, from light fans to enormous engines and dynamos, against the transmission of vibration and noise.

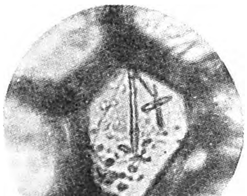
The seventh property of cork—its high coefficient of friction—has been put to use only since the machine age came in. When cork bark is sliced cleanly, a surface is created exposing tens of thousands of hexagonal open cells to the square inch, each acting as a tiny vacuum cup. This, and the unusual resistance of the cell wall to frictional wear, gives cork the gripping and polishing properties now widely utilized. Plate glass mirrors and windows, fine glass and crystal, and optical lenses are polished on cork wheels. Leather and rubber both wear slick in short order, for their cell material has little of the toughness of cork's mysterious material, called "suber," which is neither cellulose nor wood fiber.

In the Lancaster testing rooms, one-inch squares of cork, belting leather, and rubber, all designed for the same use, were equally weighted and placed on an inclined plane. When the plane was inclined 18 degrees from the horizontal the leather slid down. At 28 degrees the rubber went coasting. Not until the plane was slanting 42 degrees did the cork creep down.

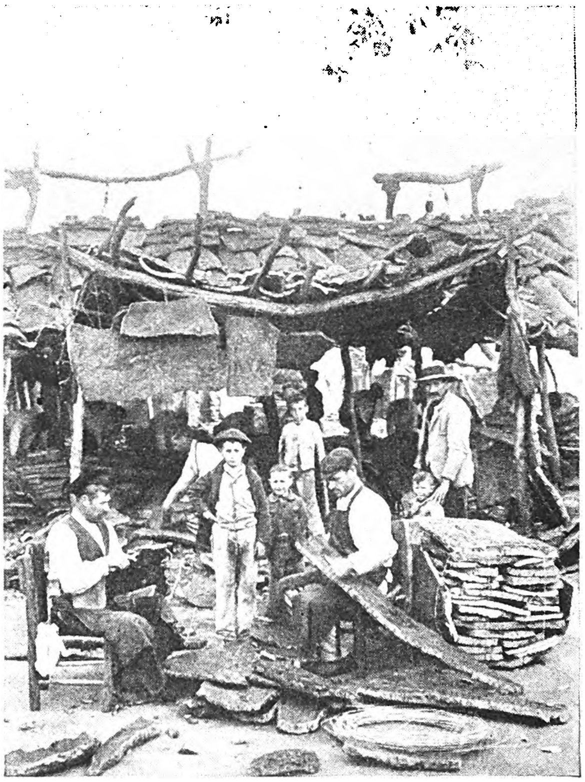
THE temptation in discussing the seven properties of cork is to wander off into fascinating bypaths to tell of the applications of cork that derive from these seven traits. They range from the tiny pieces in the pincers of pince-nez eyeglasses to the acres of cork-board, up to 12 inches in built-up thickness, in the walls of the quick-freezing meat packing plant of 1930; from the cork-lined cap of the tooth-paste tube to the newest and most uncommon use of cork in a planetarium. The first of these in America, recently completed in Grant Park, Chicago, has 9450 square feet of cork-board insulation on the dome.

The story of how and where cork grows, how it is gathered, prepared, transported, manufactured, and used, can only be sketched, for a full description of these fascinating phases would overflow this issue.

With a cork oak acreage of 550,000, Portugal leads the world with a production of 80,000 metric tons of cork; Spain is second with a production of 75,000 metric tons from 637,500 acres; Algeria is third with a production of 27,000 metric tons; while France, Tunisia, Italy, and Morocco come next in order; and even Japan produces about 400 tons of inferior cork yearly.



***Right:* Photomicrograph of the cork cell. Six cells are shown touching the central one at the point of cleavage**



Underwood & Underwood

After the cork has been cured and dried flat, it is trimmed and packed in bales for shipment

When part of a grove of cork trees has attained an age of about 20 years—for the first cutting—the expert cutters, each helped by apprentices, start to work. The expert makes a careful cut, with a tomahawk-shaped hatchet, around the trunk just above the exposed roots—in Algeria he may use a circular saw—and another just under the lowermost branches. These he connects with two vertical cuts, following the biggest natural cracks. The assistants help him pry off the bark. All this is done with the finesse of a surgeon, for any injury to the inner bark, or *phellogen,* which builds up the cork, results in a scar area over which no new cork will ever grow. This first cutting of bark, called "virgin" in Spain and "male cork" in France, will sell for a low price, to be used in the rough for florists' baskets, arbors, ferneries, and to be ground into low-grade granulated cork.

Nine or ten years later, the cutters will be back in that same grove, removing the new growth of cork, of finer grain and in every way more valuable. In some places they will also strip the bigger parts of the chief branches; in others, restrained by law or local regulation, they will wait for about five years, strip the large branches, and four years later denude the trunk again. In the French government forests—about half of those in Algeria and Tunisia—stripping the branches is prohibited. In some private forests of Spain the cutters may go back after eight years. In Portugal the law demands a wait of nine years, and the first crop cannot be removed until the tree is 15½ inches around, three feet above ground. Each crop after the first is progressively better until the tree is about 40 years old. Thereafter it may be expected to continue to produce fine cork until it dies, at from 100 to 150 years.

Copyright Underwood & Underwood

Great stacks of the cork as it comes from the trees. In foreground, a bale ready to be shipped

Virgin cork is bought with no particular care, on a weight basis. But from the second stripping on, the value of the cork makes buying a careful balance between buyer's and seller's ideas of its worth. The cork buyer is an important personage, for on his judgment profits are made or lost. He migrates with the cork cutting season, penetrates all manner of country and deals with all manner of cork grove owners, cutting contractors, and government officials.

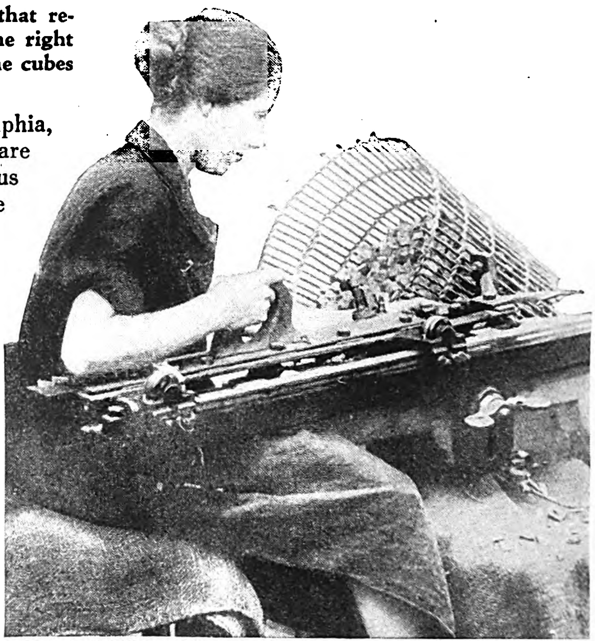
Arrived at a certain stand of cork, in advance of the cutting season—April to June in North Africa, July and August in Europe—the buyer sends his sampler through the grove on a beeline. With a cylindrical punch, the sampler cuts out a disk of cork from every 5th, 10th, or 20th tree and jumbles these in the huge sack on his back. At the buyer's office these are scrutinized with care, for on the average of them the buyer will base his bidding for so many tons of cork, perhaps for the stripping from a whole mountainside. In the French government forests of north Africa, however, the cork is gathered at stations to be sold at auctions.

To return to the typical scene, say in Spain or Portugal: The stripped cork bark is piled up in the grove and left a few days to dry. Then it is weighed on a "romana," a type of yard scale introduced by the Romans 2000 years ago. (Cork harvesting methods have changed little in 20 centuries.) The bark is carried on burro back or in carts to the boiling station at the edge of the forest nearest the market or the railroad line.

Boiling the curved slabs in large vats fired with dead corkwood softens the bark so that the rough, creviced, outer layer can be scraped off by hand with a flat tool. This process removes about 15 percent of the weight of the slab, removes the tannic acid from the cork, increases the volume and elasticity, and makes it possible to dry the slab flat. After being roughly sorted for quality and thickness, the dried bark is loaded on sturdy burros, which pick their way carefully down the mountain trails to the railway station, topheavy with a huge pile of the light bark aboard, bigger than the animal himself. As roads in Spain and Portugal are improved, motor trucks are replacing the picturesque burro.

Ewing Galloway

The cork industry in southern France is the same as it is across the border in Spain. Above is shown a girl operating a cork cutting machine that reduces strips into cubes which are later cut into bottle stoppers. At the right a girl is operating by hand a machine that cuts the stoppers from the cubes



Underwood & Underwood

ARRIVED at the warehouse and manufacturing center the crude bundles are opened and the rough edges trimmed off the slabs. Another grading for quality takes place, dividing the cork into about 25 classes. The bark for export is baled in a hand or a hydraulic press, bound tightly with iron straps, and stenciled. The bale is then ready to be loaded into the hold or on the deck of a steamer. Philadelphia, New York, or Baltimore will be the destination of nearly all of the exported crop; the rest will have gone to the stopper cutting shops nearby, the trimmings and "waste" from which will also be baled for export to the cork composition or linoleum factories overseas.

One manufacturing company has its own receiving plant at Gloucester, New Jersey, just below Philadelphia, where the various grades are separated and sent to various plants. At Pittsburgh, where the finer grades are made into bottle stoppers and other natural cork products, the final sorting puts the bark into as many as 80 bins, the grades differing so little that only the expert can detect the difference.

At this point the story of cork divides into four stems: the business of making bottle stoppers and natural cork products; the distinct processes used to make cork composition products out of scrap and grinding grades; the process carried on elsewhere which turns out cork-board for insulation, machinery isolation, and corkoustic; and the complex business of making linoleum, linotile, and other flooring material.

The key to this maze is the utilization of waste. Automatic machines punch bottle stoppers out of the best of the bark. The punched-out strips are ground into flour for linoleum or granulated for making cork composition. The coarser cork is ground into larger granules to be pressed, at high temperature, into cork-board slabs, the natural resin forming the only binder used.

Natural cork is used for pistons for plunger fountain pens and for wind musical instruments; seine and gill corks for fishing nets, and bung corks and artillery practice wads. From natural cork are also made disks for bottle crowns and patent caps, bulletin boards, penholder grips, cork balls for games, plasterers' floats, and many other products.

CORK composition is used for box toes, counters, insoles, heel lifts and pads, and bottom filler in shoes; also, in all manner of gaskets to stop leakage of gasoline, oil, or water; in churn strips, bobbers or floats for fishing lines, and so on.

In the automobile, cork and cork composition may be used in as many as 50 places, most of them unsuspected by the owner.

Linoleum is made from cork flour, as described in the October issue of SCIENTIFIC AMERICAN. Linotile, a tile of linoleum composition, is laid in special patterns by hand and produces marble and tile effects. Cork brick, non-skid, almost impervious and resistant to acids, is used in dairy barns and modern pigsties for better sanitation.

Cork carpet, made of coarser cork, is used particularly in public buildings where sound deadening is important.

Granulated and regranulated cork is used for packing fine china and glass, grapes, and other fruits. Despite modern industrial advances, cork holds its own as one of the most useful of natural substances, although it is still one of the most mysterious after 2300 years of use; in fact, it is playing an increasingly larger rôle in the drama of industrial progress.

OUR POINT OF VIEW

ACROSS THE ATLANTIC

NO transatlantic flight or attempt to make an airplane crossing of this stormy ocean since the unsurpassed flight of Colonel Lindbergh, in May, 1927, has so fired the imagination of the world as the three successful westward flights this summer. A Briton and a German made the first two flights, each with one or more stops, and the climax came when a Frenchman, already famous and a hero among his people, made a non-stop flight from Paris to New York in a plane that was also already famous for its share in his exploits.

In June, Wing-Commander Charles Kingsford-Smith, with E. Van Dyk, Captain J. Patrick Saul, and J. W. Stannage, flew from Ireland to Roosevelt Field, Long Island, in the *Southern Cross*, making one stop in Newfoundland. His flight marked the completion of a spectacular 'round-the-world air trip which had started over a year previously. In August, Captain Wolfgang von Gronau, with Edward Zimmer, Franz Hack, and Fritz Albrecht, made an unheralded flight from Germany to New York Harbor, with stops at the Faroe Islands, Iceland, Greenland, and Nova Scotia. His flight was praiseworthy for two reasons: first, because in this day of blatant exploitation of air feats, his was a surprise trip, few knew anything of it until it was over, and, so far as we know, he has not commercialized it; and secondly, because his route may prove the most feasible when transatlantic airplane services are inaugurated.

When Dieudonné Coste and his copilot, Maurice Bellonte, landed the red *Question Mark* at Curtiss Field on September 2, the final chapter in the long and tragic story of the conquering of the stormy north Atlantic by airplane was written. They had taken off from Paris 37 hours 18½ minutes previously. To these two daring fliers go, therefore, the laurels for the first non-stop crossing of the north Atlantic by airplane from the continent of Europe to the United States. They have accomplished what many others before them had tried and what they had unsuccessfully attempted in 1929.

Aviation owes much to these pioneers of 1930. When and if airplane service is started across the Atlantic to and from the United States, the lessons learned by their flights will have much influence in the choice of routes, modes of operation, and so forth. But we consider that the pioneering has now been completed except in cases where totally different types of planes—such as the Dornier *DO-X*—may be involved, and will frown upon any further individual attempts to conquer the Atlantic. Such transatlantic flights will seem to us to have the taint of commercialism or to be inspired by individual desire to exalt an already inflated ego.

GAS FROM THE EARTH

ON page 380 of this issue we publish the story of the amazing growth of an industry about which little is known: that which has been and is being built up around natural gas. Possessing about twice the heating value of artificial, or manufactured gas, this natural mixture from the earth's reservoirs has been used commercially for over 60 years but has only recently become an industry of huge proportions because of recent technical developments that have shown the way to discovery of large natural gas reserves and have made possible long distance pipe-lines.

During the current year, the natural gas industry has expanded at a greater rate than perhaps any other industry of importance—and that despite world-wide business depression. Its increase in pipe-line mileage from 80,000 to 90,000—including pipe-lines put into operation and also those on which construction has been started—represents an increased capacity of more than 12½ percent. *The Lamport Review* estimates that this 10,000-mile increase adds "at least 250 million dollars to capital investment" in the industry.

Truly this is the bright spot on the business horizon. It puts to shame many other industries that have not progressed this year—yes, despite the depression—and teaches a lesson of research and development, far-sighted belief in the future and rapid expansion. The confidence of the men behind it is worthy of the highest praise.

FUTURE AIRSHIPS

SHORTLY after the successful flight of the *R-100* from Cardington, England, to Montreal, Sir Dennistoun Burney, its designer, outlined a new proposal to establish a transatlantic airship service in which he attempted to prove that a company possessing four or six new ships twice the size of the *R-100* could operate with profit.

Such proposals are not new, but the fact that this one takes such definite form indicates that the time when a transatlantic airship service of some kind will be a commonplace thing draws rapidly nearer. In the face of this fact, American vision apparently does not see as far ahead as does Sir Dennistoun. We have under construction two airships that will be far larger than any heretofore built but beyond construction of these two we have no plans for the future—unless they be deep, dark secrets. And even for each of these two dirigibles, we are importing eight Maybach engines from Germany. This may have no very great significance but to us it is indicative of the passive interest of American engine manufacturers in the development of American airship engines.

One of the many criticisms of the dirigible is that it is bulky. True, but *The Engineer* (London) points out that its weight per passenger is only 1.56 tons as contrasted to nearly 24 tons per passenger of the liner *Mauretania*. Fuel consumption is not considered excessive; and transatlantic passenger and mail rates little in excess of steamer rates are to be expected.

But aside from all such arguments, the airship is with us and we believe it will stay, although no one can predict its ultimate status. Why, then, American apathy toward developing it to the fullest extent? Much experimental work is yet to be done but we should like, particularly, to see some intensive research done toward developing an American airship engine.

INTERNATIONAL AFFAIRS

Navy Day

OCTOBER 27TH, Theodore Roosevelt's birthday, is Navy Day, and at every Navy Yard and on every man-of-war the Navy personnel will be at home to the American people. All who can should take the opportunity to visit the nearest ship or station, to show their interest in the officers and men who are our first line of defense.

In time of war we lavish praise on our Navy; in time of peace we are too likely to forget it. We take the efficiency

RADIO CHARTS THE UPPER AIR*

By JEROME D. VAN BRAKLE

SIGNAL CORPS engineers of the United States Army have devised a means by which radio can be used to determine air conditions several miles above the surface of the earth, and after more than seven years of experimentation they have perfected, at the Signal School laboratories at Fort Monmouth, New Jersey, equipment by which the direction and velocity of the winds at high altitudes may be computed with a high degree of accuracy regardless of visibility.

Visual observations of upper-wind conditions are impossible at night and when visibility is reduced by low-lying clouds or fog. Since many war operations are carried on behind smoke screens or after dark, it became necessary to devise a method of obtaining the desired upper-air information under these conditions for Army use. The radio method was the answer to the problem.

THE radio device, perfected at Fort Monmouth, consists of a miniature continuous-wave transmitter which is sent aloft by means of three hydrogen-filled balloons. Its flight is followed with a loop direction finder, a process known as "tracking" or making a "balloon sounding." Long research was necessary before an efficient direction finder was perfected, as it was found that the commercial instruments used in radio compass work were not sufficiently accurate for meteorological use.

The loop direction finder consists of a specially-built radio receiver of rugged construction connected to a loop antenna composed of a single tube of copper, mounted on a tripod base. To the shaft of the loop is connected a calibrated dial, graduated in degrees and fractions. This dial is used to measure the angles through which the loop turns. Except for the fact that the receiver is of the regenerative type, Signal Corps authorities refuse to divulge the details of its construction.

The transmitter which goes aloft with the balloons is compact and sturdy and weighs less than a pound. It consists of a small vacuum tube, an inductance coil of enameled wire, a small transformer, and a small flashlight battery, the whole outfit costing about five dollars. When the battery is snapped into place at the bottom of the device, continuous-wave oscillations are started which will continue for more than two hours. This wave has been picked up from a distance of 15 miles.

The length of wire which connects the transmitter to the balloon cluster acts as an antenna. Signals are sent at a constant frequency of 2300 kilocycles or 130.5 meters.

When the balloon cluster, carrying the transmitter, is liberated it ascends vertically, because of the hydrogen gas, but at the same time it is blown about by the winds it encounters. This lateral motion is recorded by observers and from the data obtained, the speed and direction of these winds may be accurately determined.

It has been found that the cluster will rise at the rate of approximately two hundred yards a minute and that this rate of ascension will continue until the internal pressure of the hydrogen gas exceeds the outer pressure of the rarefied atmosphere and one or more of the balloons burst. Usually only one bursts and then the others act as a

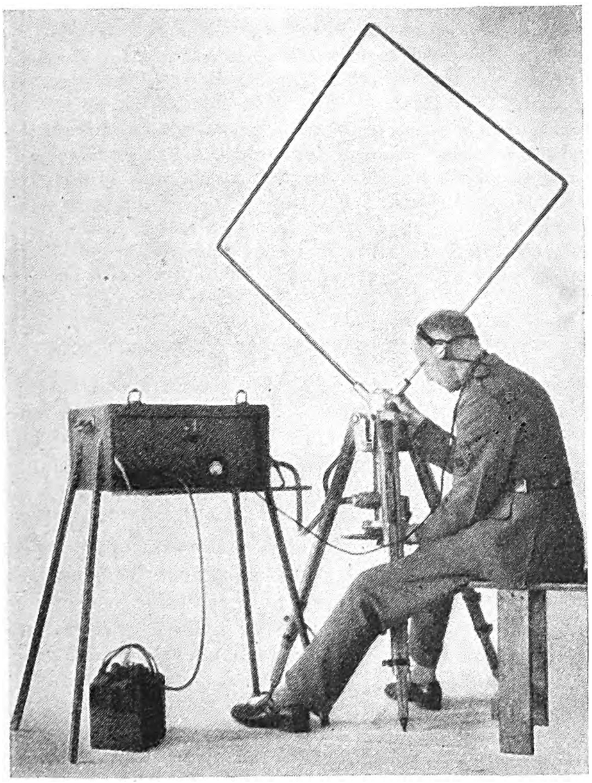
parachute and gently lower the apparatus to earth with little damage.

While the balloons are in flight, observations are taken by two direction finders set up on a base line of known length. Experiments have shown that this length should be three miles for the best results, although shorter distances have been used with a high degree of accuracy. Sometimes three instruments are used; then they are set up in the form of an equilateral triangle of known sides. The third instrument, however, is used principally as a check on the others.

AFTER the release of the balloons, operators obtain bearings on them every minute. Accurate time is given by a clockwork device which emits a howl at the end of each minute and a warning buzz ten seconds before the minute. The bearings are telephoned to an observer at a plotting board where they are entered on a scale map. The point of intersection of each set of two bearings shows the exact position of the transmitter at any minute. From these data it is simple to determine the horizontal flight of the apparatus and by means of a special protractor and a wind scale, the required velocity and direction of the wind at each level of altitude is computed. Balloons may thus be tracked for several miles.

The observers at the loops base their calculations upon the zero point, where the signals from the transmitter are not heard. The loop is revolved until the signals disappear and the angle is read from the scale on the shaft of the loop.

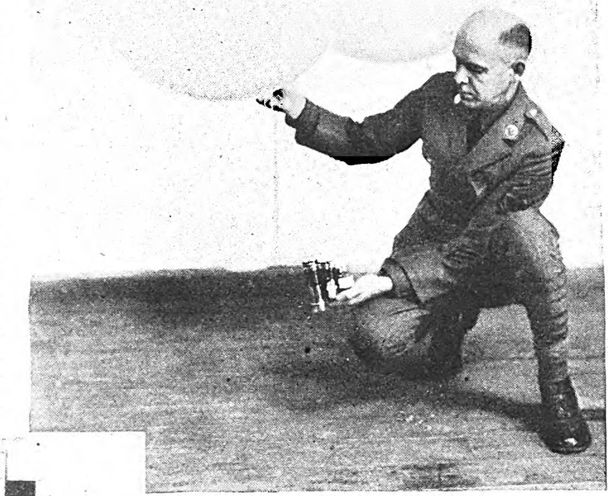


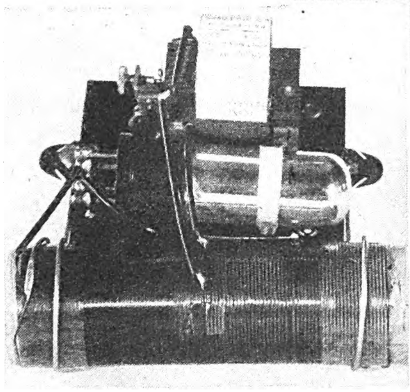
The direction-finder loop in use. The operator swings the frame, listens to the signals, and reads the angle

At the zero point, the plane of the antenna is at right angles to the direction of the transmitter. One of the points of high efficiency of the Army receiver is that the zero point does not vary until the transmitter is more than three miles from the receiver, then the variation is so small that accurate results may be obtained for seven miles and usable results for several miles further. Experiments have shown that the zero point in commercial sets splits before the transmitter is a mile away, greatly lowering the efficiency.

While the new system was undergoing preliminary tests at Fort Monmouth, simultaneous readings were made by radio and visual methods. These experiments showed that the radio method gives more accurate results as the continuous signal can be more easily traced. The visual method is more commonly used, however, because of the greater distance possible and because of the economic phase.

In the Atlantic seaboard states, where the prevailing winds are easterly, most of the instruments sent aloft are lost in the ocean, but in the Middle West, 95 percent of the transmitters are recovered. To insure the return of as many of the transmitters as possible, a notice is attached to the set offering a small reward to the finder if the instrument is sent back to the base station.





Above: **The one-pound short-wave transmitter attached to balloons.** *Left:* **A close-up of the transmitter. The battery is behind the instruments**

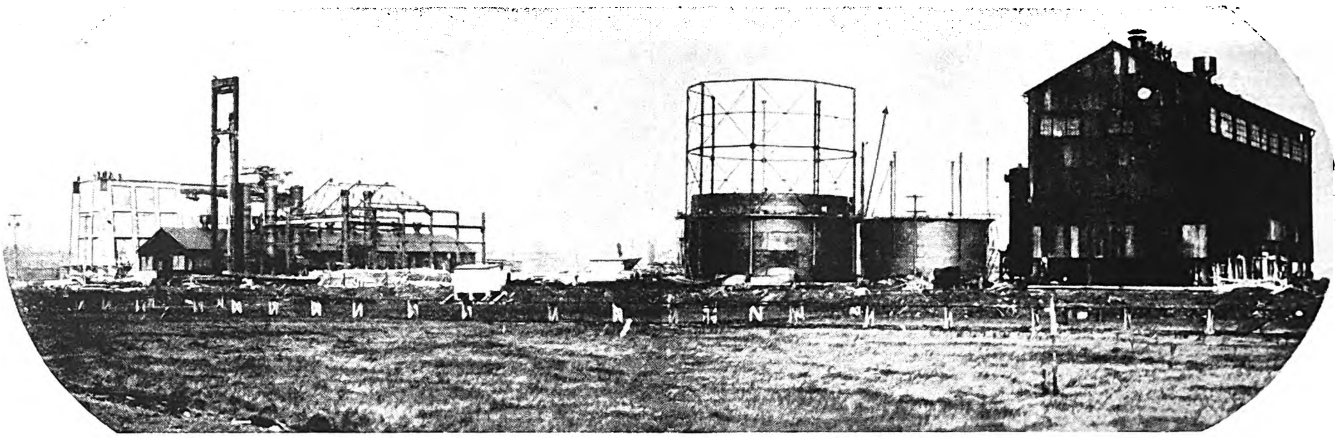
At Fort Monmouth, one day recently, a farmer drove up to the reservation in a dilapidated farm wagon. He walked up to the meteorological officer and handed him one of the transmitters which had fallen on his farm.

"You came mighty near not getting this contraption back," he declared. "When it came fluttering down in my cornfield I thought it was some new kind of bird and I almost wrecked it with my shotgun."

Although many of the instruments are returned in peace times, few recoveries would be expected in time of war. The cost of the apparatus in comparison with its utility and the value of the information it gives is so small that little thought would be given to the loss.

AT the present time, radio officers at Fort Monmouth Signal School are experimenting to find a method of determining upper-air temperatures by radio. A bi-metallic plate of variable capacity at different temperatures has been inserted in the circuit of the transmitter just described. It is designed so that the wavelength will vary as the air temperature increases or diminishes and these wavelength changes will be noted on the ground by means of suitable instruments.

Now that the common wind vane has been lifted high into the air by means of radio, it is the ultimate aim of these agents of Uncle Sam to use the radio device, with variations, to unfold many other secrets of the upper air currents.



Hydrogenation plant of the Standard Oil Company of New Jersey under construction at Bayway

A GALLON OF 'GAS' FROM A GALLON OF OIL

By HENRY W. HOUGH

"OIL DIPLOMACY" is the title of a long chapter in Ludwell Denny's arresting new book "America Conquers Britain" (Knopf), a remarkable record of economic war which is taking place today on a worldwide front in the form of bitter struggle between America and Britain for world markets in major commodities. The struggle takes its most violent form in oil. The most powerful world participants in the great contest are the vast Deterding interests (Shell) of Great Britain pitted against the Standard interests of America. The oil reserves of the smaller nations—Persia, Mexico, Colombia, Venezuela, and so on—are the rich fruits of battle. The accounts of some of the dealings between the rival giants make fascinating if somewhat grim reading; the international oil war is not a game of tiddleywinks. Ostensibly the oil war between America and Britain is conducted by private interests but Mr. Denny reveals that both governments have taken a hand. And why not? Oil is a national asset; without it no nation today can remain a first class power. Britain is not losing the oil war; we are. She has largely outwitted us, gaining control of the best resources. We are left holding the bag. "The public has been in no mood to champion the cause of any oil company at home or abroad," Mr. Denny writes, "but this sentiment is changing. The danger point will be reached when a near-shortage drives prices upward and American automobile owners are told the British have cornered most of the world supply." Britain is keeping much of her own oil supply intact and cleverly finding ways to exhaust ours. The Bergius processes, described in Mr. Hough's article, are German in origin and Standard has obtained them, but the cheapest oil at present comes from the ground. When the American people finally wake up about the oil situation will it be too late?—*The Editor.*

LAST season, or perhaps it was the preceding season, a thrilling drama was witnessed by theatergoers. It involved a young genius who had made a scientific discovery of startling significance. He proved that he possessed the power to blow the world to smithereens. His secret was known only to himself. Anxiety and apprehension resulted—until the closing scene of the play.

Another drama almost equally exciting although somewhat less sinister now is being enacted before a much larger audience. The opening scene was in a laboratory in Germany, and centered about the research of the noted investigator, Dr. Friedrich Bergius. The scientific world was amazed by the news concerning his hydrogenation process for converting wood into coal, coal into oil and gasoline, and so on.

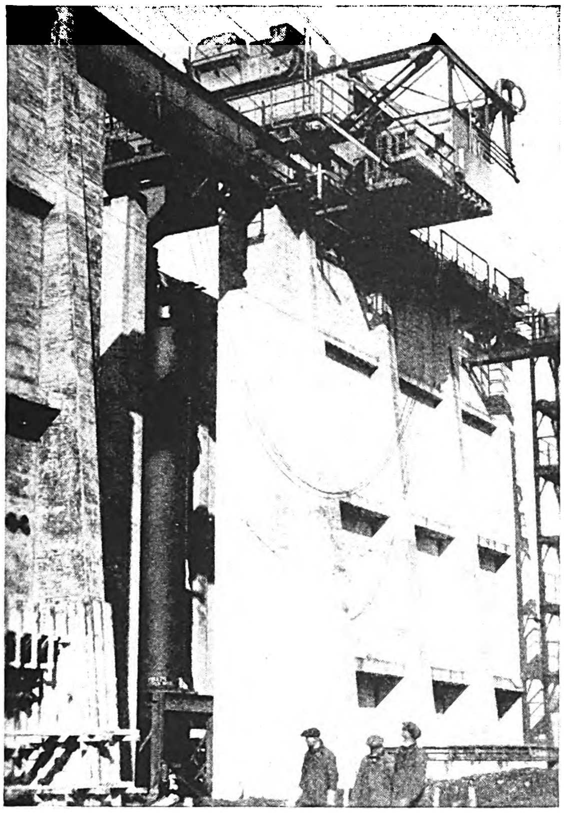
NOW the scene has shifted to America. About a year ago the rights to Dr. Bergius' process were acquired by the Standard Oil Company of New Jersey, in affiliation with the I. G. Farbenindustrie or "Dye Trust" of Germany. With the news of this merger, which followed three years of co-operative examination of the technical and commercial possibilities of the process, there came another startling announcement: "It now is commercially practicable to produce 100 gallons of gasoline from the running of 100 gallons of crude oil, by the addition of gaseous hydrogen under high pressure and high temperature in the presence of certain catalytic agents."

These developments have aroused rather than allayed the fears of those who anxiously await the outcome. Will the next scene show chaos in the petroleum industry? With over-production of oil constantly worrying the producers, must they now face a flood of cheaper "artificial" gasoline?

The petroleum industry has waited rather impatiently for further progress reports. The general public has exhibited similar interest, for today "the man in the street" is not only a consumer of gasoline and oil, but also is on the lookout for investments which seem to have great potentialities.

With the opening, a few months ago, of the first of three 5000-barrel-a-day hydrogenation plants, it seems that the Bergius process at last is ready to become an important factor in the petroleum industry. The first commercial plant is located at Bayway, New Jersey. Two others are to be built soon, one in Louisiana at Baton Rouge and another in Texas at Baytown. These plants are more than experiments, for each is a large-scale commercial unit based on the results of several years of intensive research and development. No effort has been spared to perfect the conversion apparatus and the methods of operation best suited for commercial production of gasoline and light oils.

To the layman, who may have grown weary of hearing about over-production in the oil industry, it may seem that hydrogenation has been born too soon. Even in the face of solemn warnings that the world's supply of petroleum



The retorts (inside the concrete structure) in which the hydrogenation takes place at Bayway

can last only a few more generations, there are many who feel that at present there is no place for any revolutionary method of producing motor fuels. However, the situation takes on a different aspect when one is familiar with the other great developments which have led up to the present state of affairs.

When the oil industry was very young, there was a well-distributed demand for all of the important products of petroleum. Then the market for illuminating oil stepped ahead of the others. While meeting the demand for kerosene, the refiners found that something had to be done about disposing of the rest of the products.

The solution was found in a new process, by "cracking" the heavier fractions of the crude oils in such a way that a larger proportion of kerosene was obtained. Crude oils which normally yielded 20 to 30 percent of kerosene were made to yield from 50 to 70 percent by this revolutionary step.

SOME time later, the situation took a new turn. Gasoline became the most valuable fraction, and the demand for kerosene declined. Again something had to be done about utilizing the less valuable products, and again the solution was found in improving the process. It proved to be considerably more difficult to increase the gasoline yield, but the result was nearly as good as when effecting the decomposition into kerosene fractions. At the present time about one third of the world's total demand for gasoline is met by "cracking" or conversion, rather than by refining.

With this background, it is easy to see where hydrogenation fits into the picture. With the ever-growing demand for gasoline and light oils, there has been constant over-production of the less valuable products, the heavy oils. The market has shown that it does little good to lower the price of this class of fuel. There simply is little demand for it.

Careful examination of the cracking process does not give any grounds for presuming that the problem can be met by an improvement in technique with the present production methods. Attempts are being made to perfect the Diesel engine to so great an extent that it will operate satisfactorily on the inferior grades of fuel oil, as it now does on the better grades. Research in both of these fields is yielding some very commendable progress, but there seems to be no justification for high hopes. Meanwhile, the world has an enormous over-supply of heavy fuel, and the market for the more valuable motor fuels has not yet neared the limit of its elasticity.

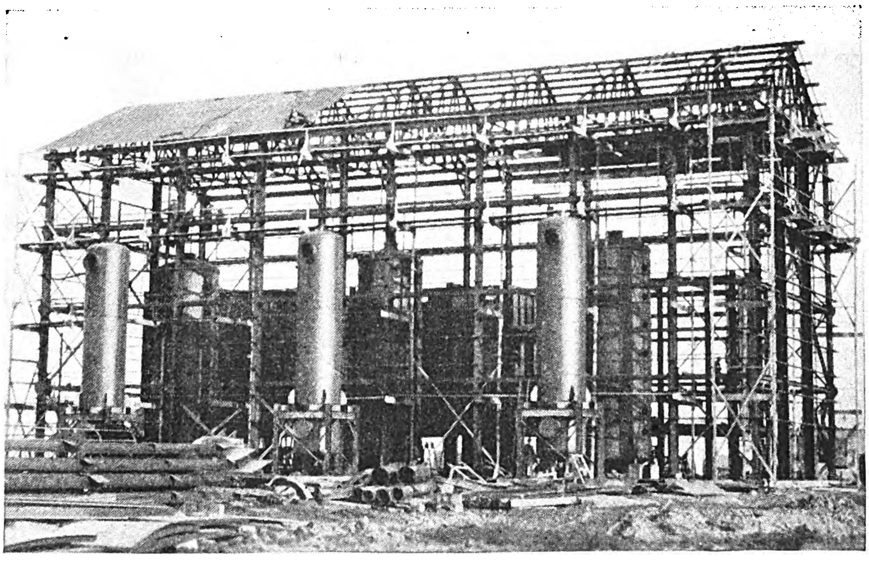
From this it is clear that there is need for a new manufacturing process which can make profitable use of the petroleum products which now are a drug on the market. The hydrogenation process, in its present state of development, is more than capable of meeting this need. This process has shown its ability to do greater things than convert heavy oils into gasoline.

Dr. Bergius took several steps at once when he worked out a method for converting wood into gasoline. First he duplicated nature's "incoaling" process, by which he quickly transformed wood or other vegetable matter into coal. Then he went on with the same process, converting the artificial coal into oil. It was found that the same thing could be done with natural bituminous coal. The hydrogenation of heavy oils into gasoline and light oils is but a page in the story of Dr. Bergius' achievements.

After enumerating that remarkable series of advances, the writer scarcely dares mention Dr. Bergius' one great purpose, an unfinished performance which may yet make these others seem like mere side-shows. Underlying all of his research is the greatest objective of all—to perfect a practical process which will enable man to make his own food, and food for his animals, by utilizing apparently worthless materials which now are burned as rubbish.

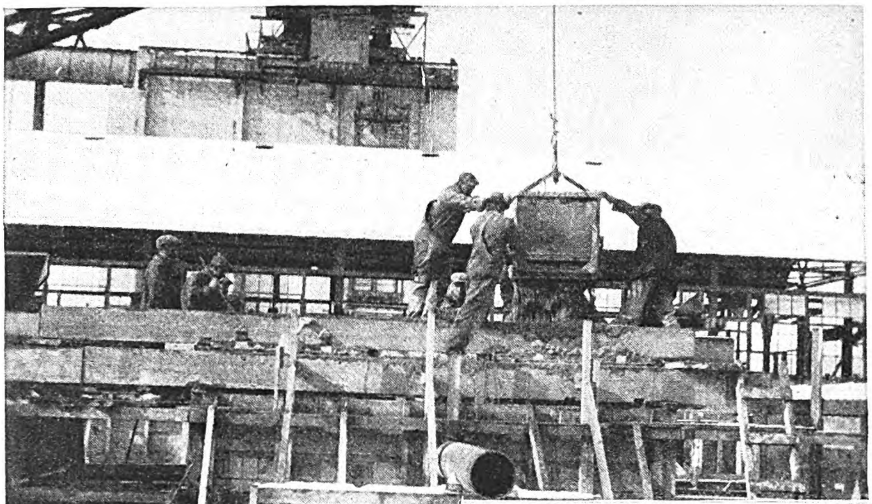
RETURNING to today, after this glimpse of the day-after-tomorrow, we can look more deeply into the process which now is being used to produce gasoline from almost worthless heavy oils. Of paramount importance in this conversion process are the toxin-proof catalysts. These make it possible for the gaseous hydrogen, which is introduced into the high-temperature conversion apparatus under exceedingly high pressures, to transform the molecules of the heavy oils into molecules of gasoline and other light fractions.

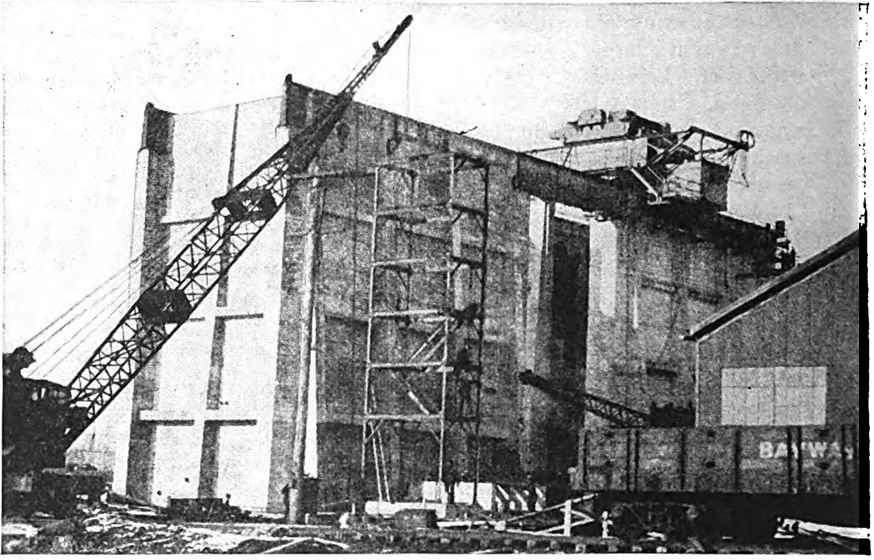
It might be well to add a word of explanation about catalysts, for the benefit of those who find the term an unfamiliar one. In chemistry, a substance which serves the useful purpose of stimulating or facilitating a reaction, without adding to or detracting from the



Where the hydrogen will be manufactured—the gas plant building under construction. The new process consists essentially in adding hydrogen to the oil materials involved, is known as a catalyst. In matrimony, a person who plays a similar rôle is known as a matchmaker. In both instances, they may be very helpful.

Years ago, Dr. Bergius effected the conversion of wood into coal, at a temperature of about 340 degrees, in the presence of water in liquid form. A pressure of about 200 atmospheres was provided as a means of keeping the water from vaporizing at such high temperatures. The water served to prevent super-heating of the newly-made coal, and made it possible to control the physical conditions during all phases of the incoaling reaction.





Upper: **Pouring some of the 4700 cubic yards of concrete that went into the Bayway hydro plant.** *Lower:* **Huge concrete slabs enclosing the reaction towers in which hydrogenation actually takes place. Overhead is a traveling crane**

In his coal liquefaction process, Dr. Bergius used ferric oxide with the hydrogen, in apparatus designed to withstand pressures up to 2000 pounds per square inch. At a temperature of 400 to 500 degrees, Centigrade, under a pressure of about 150 atmospheres, the conversion into oil and gasoline took place. The catalysts now used with the Bergius process, as it has been improved for the commercial production of gasoline and light oils, are considered a secret. There also is great secrecy about the exact temperatures and pressures used, and other features such as the design of the high-pressure conversion apparatus.

OTHER investigators, Satatier and Senderens, had found that a nickel catalyst aids in the production of methane gas from coal. The Fischer process of hydrogenation produces benzine by using iron and cobalt as the catalytic agents, and high pressure is not required. In this instance, the catalysts tend to inhibit the formation of methane, and when caustic alkalis are added the conversion continues on down to solid paraffins.

The Bergius process now is being adapted for the conversion of gasoline from heavy crude oils, such as that produced in Venezuela. By present methods of refining and cracking, only a small proportion of gasoline can be extracted from these heavy crudes. Most of the residue is heavy fuel oil, for which there is practically no demand at present.

In the hands of almost any other industrial organization, it might reasonably be feared that the exploitation of the hydrogenation process would bring about chaos in the petroleum industry. However, because of the Standard Oil Company's enormous investment in the oil industry, it is felt that the owners of the hydrogenation process will move with extreme care in order to avoid changing the *status quo* to any great extent.

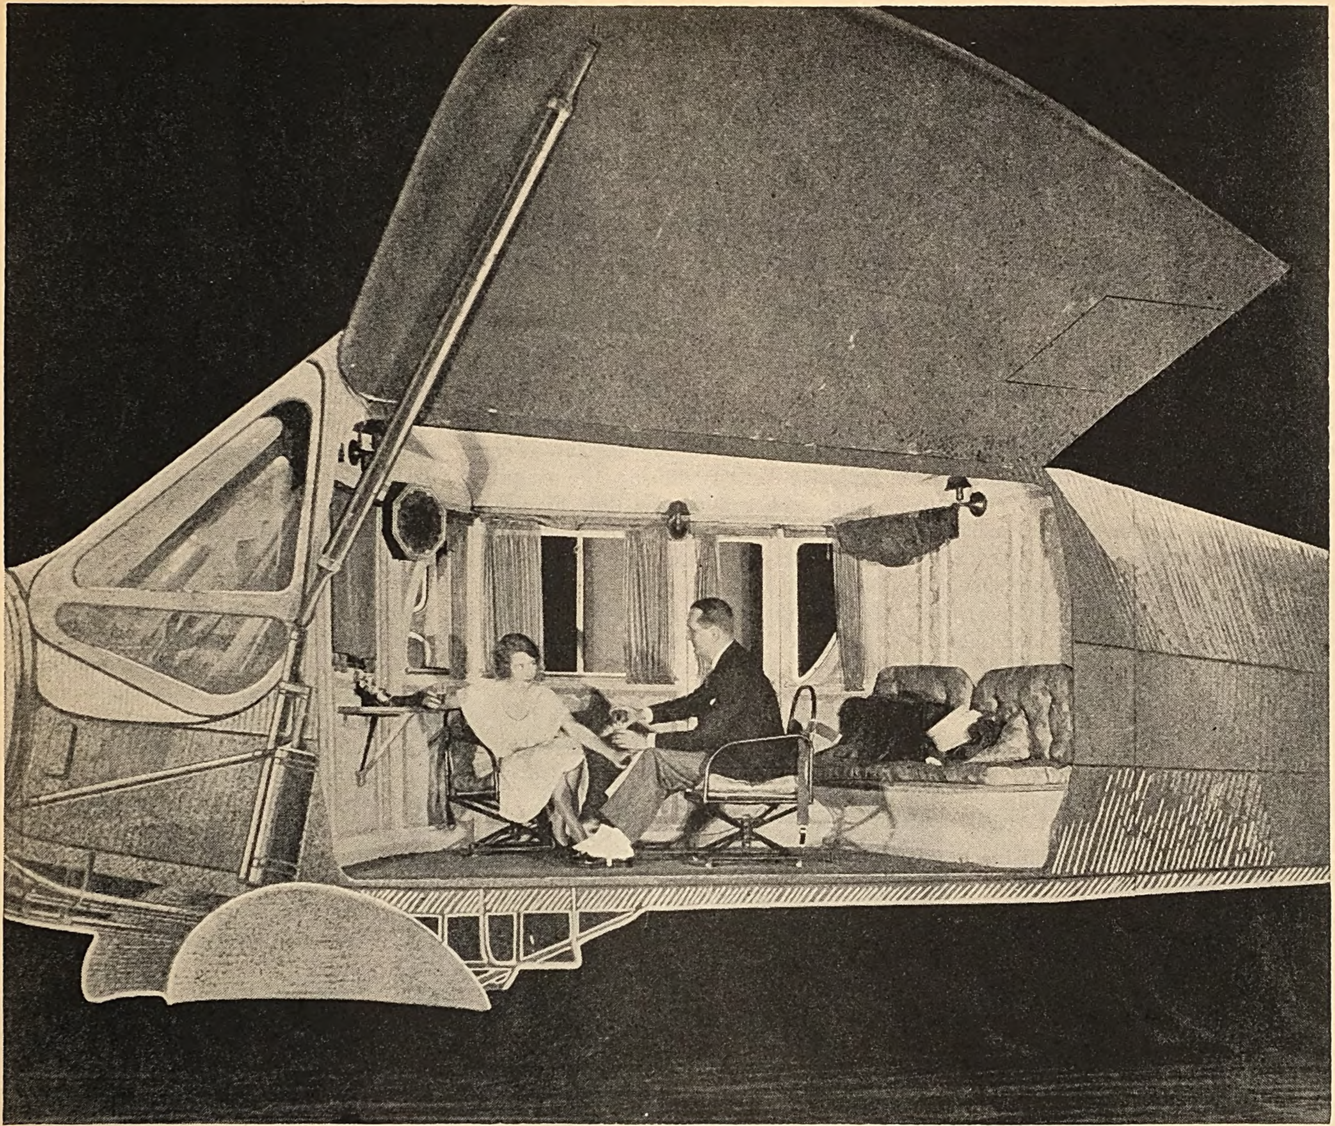
The rights to use the new process in the United States will be leased to other oil companies. Licensing companies will purchase stock in the Hydro Patents Company, a subsidiary of the Standard-I. G. Company, at the rate of one share of stock for each barrel of daily hydrogenation capacity. For example, a firm desiring to establish a plant to produce gasoline at the rate of 20,000 barrels a day will buy 20,000 shares of stock in the Hydro Patents Company.

These outside firms also will be required to align themselves with another subsidiary corporation, the Hydro Engineering and Chemical Company. This organization will furnish the technical information and will supply the catalytic agents. It also will act as engineer in designing, constructing, and supervising the plants of licensees.

ACCORDING to Mr. W. C. Teagle, president of the Standard Oil Company of New Jersey, the future of the oil industry will be determined by the extent to which both producers and refiners recognize that it is not a question of the volume of the products which governs their destiny. It must be realized that the real test is in the industry's ability to measure production to fit the requirements of the consuming markets. The probable effect of hydrogenation upon the petroleum industry is best expressed in Mr. Teagle's own words:

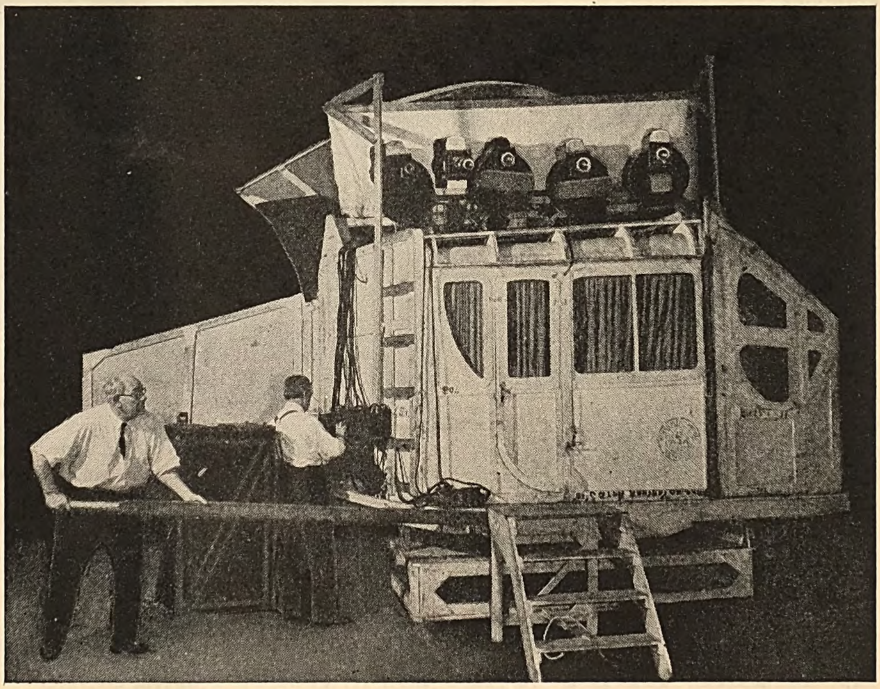
"Through hydrogenation it now is shown to be practicable to convert coal into liquid hydrocarbons at a cost which, although above prevailing oil prices, is not prohibitive. Thus, the coal reserves of the world become supplemental to the crude oil reserves.

"Because of the innumerable new technical problems, solutions of which are required for the practical and profitable use of the hydrogenation method in the oil industry, and because of the relatively large investments required, progress toward its general application will probably be slower than was the case with the cracking development. The ultimate effect, however, should be even more important."



THE STAGE GOES "AIR-MINDED"

ANY play which goes through the hands of David Belasco is sure to be elaborately staged with a fine feeling for detail by this rare artist. His latest production, called "Dancing Partner," has a scene where the lovers are taken aloft in an airplane which cavorts around while fleeting terra firma, clouds, and the starry heavens are viewed through the cabin windows. These illusions are produced by means of projectors carried on the top of the airplane, hidden from the audience by a wing and projecting directly on to the back drop. The electrician controls these effects from the side of the airplane. The huge loudspeaker for the engine effects is located at the left behind the operator who is giving motion to the plane. Another speaker in the dummy cockpit simulates the noise of the propeller and, together with the motions of the landscape and clouds and the sliding passenger seats, serves to give realism to the scene.



EARTHQUAKES

By G. AUSTIN SCHROTER

MANY bizarre theories are prevalent in the popular mind as to the origin of earthquakes and many other unrelated phenomena have been attributed to them, yet they are quite ordinary and commonplace natural processes originating within the outer crust of the earth.

The great Japanese earthquake of 1925 was probably the greatest catastrophe of modern times, and since its advent, Japanese scientists have been among the leaders in seismic studies as well as pioneers in the science of earthquake precautionary measures. Aside from the purely geologic phase of their studies, the Japanese have inaugurated a hitherto undreamed of architectural era in which beauty and safety from crustal movements have been combined.

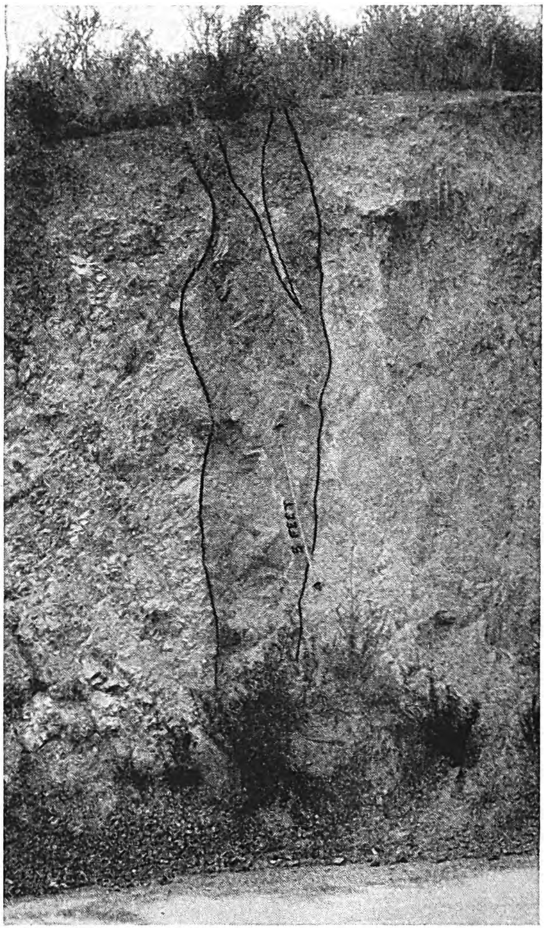
FOR innumerable years scientist and layman alike believed the source of all seismic activity to be in volcanic activity. Although it is quite true that many sharp local shocks owe their inception to volcanic action, in the aggregate volcanism is rather a subordinate cause of major earthquakes.

There are several types of volcanoes whose classification is dependent upon the types of their eruptions.

The quiescent type, of which Mauna Loa and Kilauea in Hawaii are typical examples, completely lack the catastrophic phenomena of the volcanoes mentioned below. The quiet types give rise to outflows of intensely hot lava, without violent projection of gases or solid material; much as a pot of mush will quietly overflow its container and run down upon the stove top. Quite frequently the pent-up lava content will break through the sides of the vent and peacefully roll down the sides of the volcano until it comes to rest on the slopes below. This type of volcano is of relatively slight importance from the seismic standpoint.

The intermediate (Vesuvius) type of volcano stands midway between the quiet and explosive varieties, and quiet outpourings of lava may be preceded by or alternate with periods of violent explosive activity. This is by far the most common type of volcano, and although local tremors may have their birth in this type of eruption, they usually are of unimportant magnitude.

The explosive type of volcano is, as the name implies, marked by violent explosive activity during the eruptive stage, and sudden ejection of gases, dust, and rock fragments is typical. The most outstanding example is Krakatoa, located in the Straits of Sunda near Java. In the eruption of 1883, Schuchert says that "after premonitory outrushes of gas for some time, the great explosion occurred which blew away over a cubic mile of material from the volcano! The vast cloud of ejected material arose over 17 miles into the atmosphere, completely hiding the sun . . . over a vast area. The noise of the detonation could be heard for over 150 miles, and the atmospheric disturbance affected barometers all over the world!"



All photos by R. C. Bowes

A fault showing at a road cut. The black lines were drawn in, as the materials were poorly distinguishable in the photograph. They delimit the zone of crushed, ground-up granite. Note the uncrushed pendant within the crushed zone

Small wonder then, that some violent volcanic outbursts give rise to sharp, disastrous, local shocks. These may be due to the effect of the actual detonation on the surrounding rocks, or they may be due to collapse of the crust due to extravasation of underlying lava, just as a building will be weakened and finally collapse if the foundations are gradually removed. Still another explanation of earth tremors in connection with volcanic activity is the sudden violent shattering of hot rock in contact with steam or cold water. This process is similar to the old trick of shattering rocks by heating them in a fire and suddenly quenching them in water. There is little or no proof for this theory of rock-bursts.

IN the year 1811, the lower Mississippi valley was visited by a series of shocks, many of them catastrophic in magnitude. New Madrid in southern Missouri was demolished, and this earthquake was named after the town. Much of this region is an area of limestone rocks which are relatively soluble in circulating ground waters, as indicated by the many limestone caves which abound in the region. It has been suggested that one of the contributory causes to the New Madrid earthquake may have been the sudden collapse of the roofs of certain of these caverns due to the weight of overlying rock masses. It is, however, obvious that other factors must have entered into the case as the shocks were too heavy and too widespread to have originated in this manner alone.

This leads us to a consideration of the most outstanding and common cause for earthquakes, especially of the more sudden, heavy, and frequently disastrous shocks.

That the outer crust of our old earth is constantly undergoing alteration and modification is a fact patent to the most unskilled of observers. The mighty forces of nature seem to be forever in a state of unrest, and they are constantly at work in their task of altering, shifting, and disintegrating the strongest of rocks and the mightiest of mountain ranges.

The sea reaches eager fingers to the land, and the sea waves with their burden of sand and littoral material wear away the land, under-cutting the strongest of cliffs, and piling the waste material in spits and bars. Tiny drops of rain fall upon the earth and, as each follows the path to the sea, does its finite bit in wearing and transporting the small products of rock decay. Rills, rivulets, and rivers scour their channels and sweep away portions of the banks, ultimately to deposit their load of silt and sand in the ocean or on some lower flood plain. Winds loaded with dust and sand abrade the toughest of rocks and carry the products of the disintegration many hundreds of miles before they are dropped. Glaciers pluck away whole mountains and move them away. Thus, even the mighty continents themselves are in motion! Throughout the vistas of geologic time mountain chains are worn away and new ones are thrown up to take their places. All of nature is at work in the age-old processes of tearing down and building up.

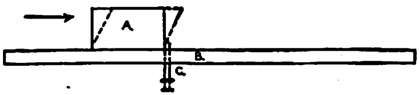
AN attempt to discuss the details of the stupendous forces of mountain making or of the uplift and subsidence of land masses, would require much space, but it becomes increasingly obvious that, when millions of tons or hundreds of thousands of cubic miles of rock are moved from one portion of the earth's crust and deposited upon another portion, adjustment of the crust must ensue to support the gigantic loads thrust upon it.

Every beam, bulwark, or foundation must have an ultimate breaking point when the loads upon it exceed its strength. And so we find that the crust of the earth must give way in places when the load placed upon it exceeds its strength. In short, a rupture or break is bound to occur, and the broken segments in turn will adjust themselves to the stresses which are acting upon them. Such ruptures or fractures in the outer crust along which appreciable movement has occurred are "faults," and it is to them that we must turn in looking for the most common cause of earthquakes.

Proof that the great crustal blocks do readjust themselves to the loads thrust upon them is apparent on every hand. Sea shells and the remains of marine organisms are found on the highest mountains, thousands of feet above sea level, old marine strand lines and beaches are elevated far above the reach of the nearest sea waves. Man-made monuments and temples that were constructed within historical times on perfectly dry land are now found to have sunk beneath the sea and been resurrected, not once, but many times. It does not seem so strange, then, that proofs of this constant crustal unrest frequently manifest themselves as shocks, tremors, and ghostly sounds, apparently arising from the very bowels of the earth.

Movements along faults are constantly in progress. No one region is free from them, and if they happen to occur suddenly or with much friction, they are manifested to our senses, but if the slip be slight or gradual, only the most sensitive of seismographs can detect it.

No hour in the day, no day in the year, and no region on earth is free from earthquakes. They are as common as life itself, but by far the largest number are not apparent to the senses. The idea that any given region is free from earthquake danger is fallacious. In New England, for example, in the 230 years following its settlement, Schuchert says that over 230 earthquakes have occurred.



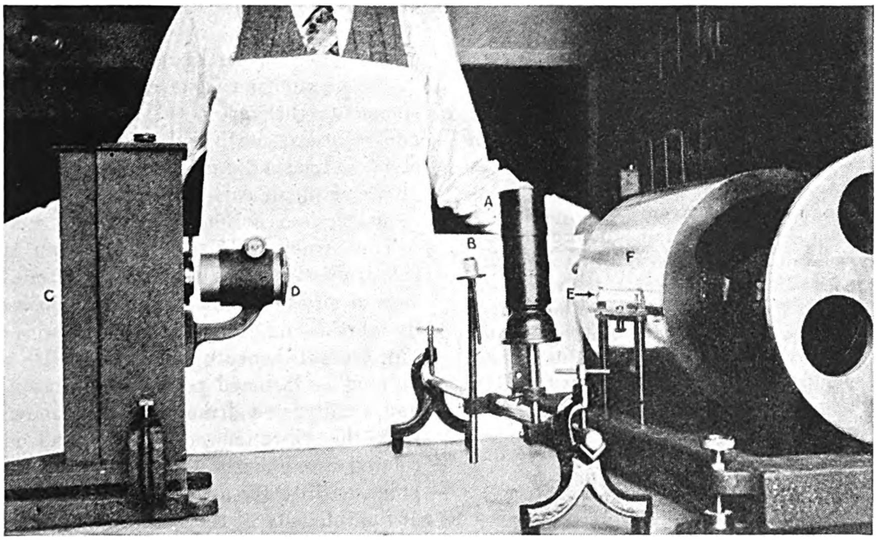
A model to illustrate the principle of elastic rebound. An India rubber block (A) sliding over a table top (B) is impeded by an upward projecting nail (C) until it tends to undergo elastic distortion. If the nail is quickly removed while the force is in operation, the elastic properties of the cube will cause it to snap into its original undistorted shape, causing an "earthquake"

Displacement along faults may be horizontal, vertical, or both vertical and horizontal, the latter being the most common type of movement. One of the most recent theories to be held regarding the origin of earthquakes is known as "Reid's theory of elastic rebound," and it may be explained somewhat as follows.

SUPPOSE that a block of India rubber is moved over a table top, as shown in the figure, until the bottom of the block is intercepted in its movement by a nail or peg driven up through the table. If the moving force continues to act, the top of the block will continue to move forward, but the bottom of the block, by virtue of the obstruction will cease to move. As a result, the elasticity of the rubber block will tend to snap it back to its original undistorted position when the obstruction is removed, and the block will assume its former shape and gliding motion with a sudden snap due to the molecular forces within it.

This process is exactly what may occur in two contiguous blocks of the earth's crust. If they are slowly moving past each other due to the stresses of readjustment, and the movement is impeded by a force tending to stop it, stresses will immediately be set up in the two blocks. The stresses will continue to grow until the moving force or the elastic tendency of the blocks overcomes them, or the rock shatters.

When either of these two phenomena occurs, it will manifest itself by a sudden sharp jar or shock, the intensity of which will depend upon the amount of deformation overcome, and upon the in-



Torsion seismograph perfected by Dr. J. A. Anderson of the Mount Wilson Observatory staff, and Dr. H. O. Wood, Research Associate of the Carnegie Seismological Laboratory at Pasadena, California. A beam of light is sent from the lamp (A) to the prism (B) from whence it is refracted to the mirror of the seismometer within the case (C). The rotating mirror of the seismometer reflects it through the telescopic attachment (D), thence through the cylindrical lens (E) to a strip of light-sensitive paper mounted on the revolving drum (F). The entire apparatus is mounted on a concrete pier within a light-proof cabinet. The optical recording system does away with many difficulties encountered in a mechanical one

tensity of the moving force. The jar will be transmitted instantly to the surrounding crust and waves will be sent out from the point of origin. These are the earthquake waves, and their physical characteristics will determine the amount of damage which they are able to do.

Some faults, quite naturally, are undergoing no movement at present, and are known as "dead-faults." Those which are at present undergoing readjustment are "live-faults." Likewise, some faults are undergoing more rapid readjustment, or are subject to greater stresses, and hence are more pregnant sources of violent shocks.

The great San Andreas rift of California has been studied more in detail, probably, than any other earthquake fault in the world. It has been traced for over 600 miles and forms the boundary between two great crustal blocks, one moving south and the other north relative to each other. It was the San Andreas rift which was the source of the California quake of 1906. In connection with this temblor, it underwent displacement for over 290 miles. Fences and roads crossing it were observed to have been broken and moved apart as much as 20 feet.

MANY earthquakes are due to vertical movement along the source-fault. For example, the great Mino-Owari earthquake in Japan showed a vertical displacement of 20 feet in one place, while the Owens Valley earthquake showed a maximum uplift of 23 feet.

Awe inspiring stories without number have been related by the survivors of great earthquakes, of the fearful sounds accompanying the shock, which were scarcely less terrifying than the quake itself. Tales of unbelievable groaning and grinding noises, of whole forests obliterated, of new streams and waterfalls formed where none before existed, of gaping fissures and dried-up wells, are commonplace and, stranger still, in the aggregate they are true.

For purposes of study, most of the sounds accompanying an earthquake are referred to the Davison sound scale, which is given below:

(1) Sounds resembling wagons, carriages, engines, or trains passing, generally very rapidly, on hard ground, over a bridge, or through a tunnel; the dragging of heavy boxes over the floor.

(2) Thunder; a loud clap or heavy peal, but most often distant thunder.

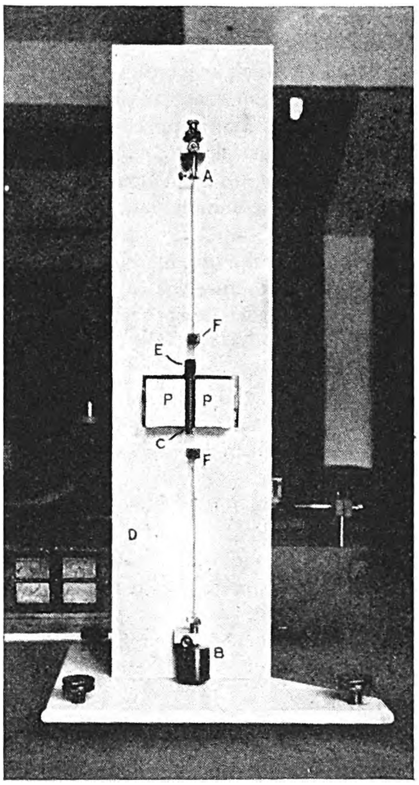
(3) Sounds resembling a moaning, roaring, rough, strong wind, a rising wind, or a heavy wind pressure against the house, a chimney on fire, and so on.

(4) Sounds of great loads of brick, coal, or rock being dumped.

(5) The fall of heavy bodies, banging of a door, pounding of the surf on the shore.

(6) Distant blasting, explosives, firing of artillery.

(7) Miscellaneous sounds such as the roaring of a waterfall, rending or tearing sounds, or the sounds of an immense covey of partridges on the wing.



Enlarged model of the torsion seismometer. A fine tungsten wire is suspended from the screw clamp (A) to the tension attachment (B). A copper cylinder (C) is mounted eccentrically on the wire. When the standard (D) vibrates, the cylinder, due to its inertia, tends to remain at rest. Torsion is set up in the wire causing rotation of the tiny mirror (E) about the suspension. A beam of light can be reflected from the mirror to a sensitized paper on a revolving drum, thus obtaining a photographic record of the shock. A magnetic field from the poles (P) damps the vibrations of the torsion pendulum. The vibration of the wire as a whole is damped by the reservoirs (F) filled with castor oil. This instrument is for use with the horizontal components of the waves. The vertical components are measured in the Carnegie Seismological Laboratory at present, on a seismometer perfected by Mr. Hugo Benioff, Research Associate

The different sounds of the Davison sound scale vary, of course, with the distance of the observer from the source of the earthquake. They may resemble the roar of a train through a tunnel in one place and the low moaning of wind in another. They may be audible to one person and entirely inaudible to another, depending upon the individual's sense of hearing. The author has many times detected the sound of thunder or heavy explosive blasts in connection with seismic activity.

The most outstanding characteristic of these seismic sounds is their extreme lowness or depth of tone, which helps to explain why they may be difficult for some persons to hear. The accompanying sounds owe their origin, of course, to the vibrations set up in the rock by the quake, just as an organ reed vibrates and causes different sounds by different intensities of vibration.

So-called "tidal waves" are another phenomenon accompanying earthquakes, especially in those of submarine origin. These waves have no relation to the tides, but are caused by the elastic rebound of submarine rock masses. In strong submarine earthquakes, the effect on ships is much as though they have struck on a rock or grated over a reef. Seismologists call these vast sea-waves *tsunamis*, from the Japanese, or when they are observed in bays or inlets, as *seiches*, especially when they are stationary waves. They may be as much as 100 or 200 miles from crest to crest, 40 feet high at the point of origin, and they may sweep across the seas with a speed of from 300 to 500 miles per hour. Such *tsunamis* may be unperceived in the open ocean, but upon reaching the land they may pile up as great waves and sweep far inland with great loss of life. Such were the waves that played havoc with Lisbon in 1755, Japan in 1854, and Peru in 1868.

EARTHQUAKES may dislodge loose masses of earth or rock, cause landslides or avalanches, and thus completely denude forest slopes, or dam streams and rivers giving rise to new lakes and "sag-ponds."

The study of earthquakes and earthquake phenomena is seismology, the instruments that are used for detecting and recording earthquakes are seismometers and seismographs, and the record obtained of an earthquake with a seismograph is a seismogram.

The principle of the seismograph is relatively simple. The instrument consists of a heavy mass of metal which by its inertia tends to remain at rest while the ground beneath it vibrates. If a pointer is fastened to the inert mass, and a calibrated drum which will move with the vibrations of the ground is rotated in contact with the pointer, the pointer will leave a record on the drum of the intensity of the shock, and of the frequency, amplitude, and period of the accompanying waves.

The classic example of the seismograph, and at the same time, one which is easily constructed, is a heavy steel ball or bearing placed on a smoked glass plate. If a shock occurs, the ball will tend to remain at rest while the glass plate under it will vibrate to and fro, and a record of the "quake-tracks" will be left on the soot.

The ideal seismograph should be able to record the wave motions in three dimensions; that is, north-south, east-west, and up and down. So far, no such ideal instrument has been devised and in practice it is necessary, if accurate results are required, to use two types of instruments, one for vertical, the other for horizontal components.

The movements of the ground during an earthquake shock may be of two kinds: (1) in large earthquakes, there may be a sudden, large displacement, or a violent lurch of the crust, either horizontal or vertical, or in both planes, or (2) as in all earthquakes, there is a vibratory motion of the ground. The measurement of the former, the great lurches or sudden displacements, can not be accomplished by seismographs. When they take place the ordinary seismographs are thrown out of action or damaged. For recording the vibratory movements, the latter, it is necessary to have two sets of seismographs, one for near, and the other for distant, shocks.

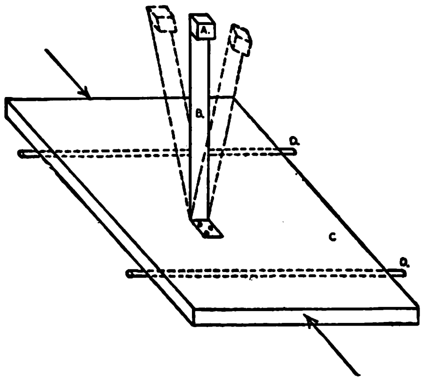
A STUDY of seismograms has indicated that the main shock is preceded by smaller, so-called "fore-shocks," and followed by slighter "after-shocks." The fore-shocks are due to the waves which have taken the shortest path from the source of the temblor to the instrument *through* the earth. The waves of the main shock are those which have traveled *around* the periphery of the earth. After-shocks are usually the result of final readjustment to stresses along the fault. In the Italian earthquake of July 23, 1930, the after-shocks continued for several days after the main, destructive shocks, and did much damage to buildings already weakened.

If three or more stations accurately record the shock, it is a fairly easy matter to calculate the origin of the earthquake. The greatest difficulty is to record the exact time of arrival of the quake at any one station so that the relative time may be determined.

The Seismological Laboratory of the Carnegie Institution of Washington, which is situated at Pasadena, California, is connected with a network of seven recording sub-stations located at Tinemaha, Haiwee, Santa Barbara, Riverside, Pasadena, Mount Wilson, and La Jolla, California. The time of arrival of a wave at any station is co-ordinated with the other stations by means of a dot-dash radiogram from a powerful, long wave, radio station. Thus, if a wave arrives at Pasadena at the beginning of a dash, and at Santa Barbara at the end of a dash, the relative time of arrival between the two stations can be calculated, and the ultimate source of the quake located.

Although, as has been mentioned, no locality is free of earthquakes, certain regions are more liable to dangerous tremors than others. These large well-defined tracts are known as seismic belts. One of them borders the Pacific Ocean, and follows the west coast of South and North America, Alaska, the Aleutian Islands, and the islands off the coast of eastern Asia. The other seismic belt borders the Mediterranean, the Alps, the Caucasus, Himalayas, and so into the East Indies.

The seismic belts follow in general the great zones of weakness in the crust of the earth. For example, off the west coast of the Americas the land is rising with respect to the ocean floor. In regions of active mountain making, great river deltas, rising or subsiding land tracts, and so on, the danger of heavy shock is more imminent.



A model to illustrate the motion in tall buildings or high stacks. The heavy metal bob (A) is mounted on the flexible brass pendulum (B) which in turn is screwed to the base (C). The base is free to roll over the rollers (D). A slight back-and-forth motion of the base will cause the pendulum to swing through a constantly growing arc

In accordance with what has been said regarding the origins of earthquakes, it would seem that in a region where many recurrent slight shocks are prevalent or common the danger of heavy damaging shocks is less. Conversely, in regions of seismic activity, periods of long quiescence may be the forerunners of a violent earthquake.

To the American people, perhaps the most horrific example of an earthquake in the rôle of a destroyer was the great California earthquake of 1906, which resulted in untold suffering, property loss, and a casualty list of close to 1000 lives. The city of San Francisco suffered the greatest loss, due in large part to the destructive fire which swept unchecked over the city following the quake, owing to destruction of pipelines by the tremors.

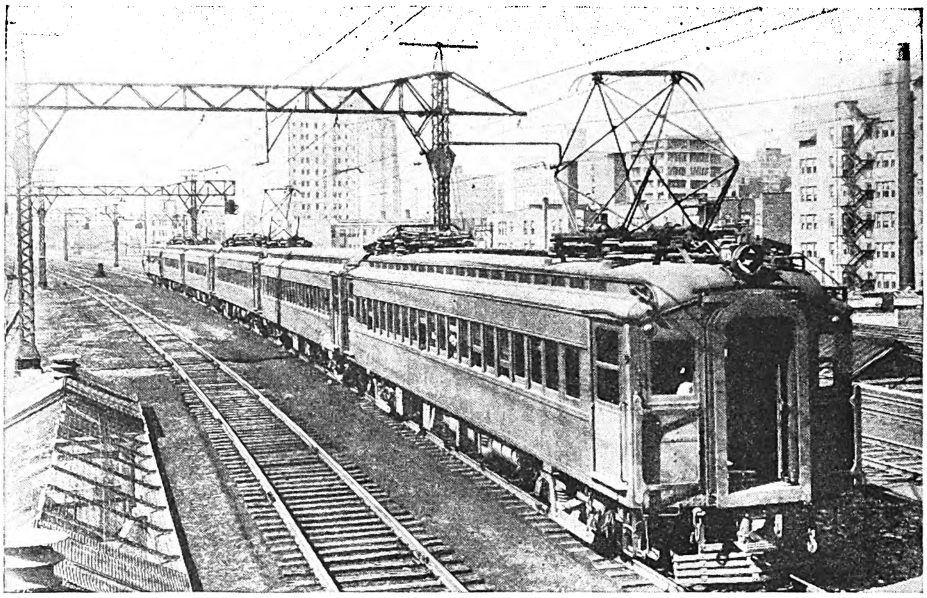
On the 28th of December, 1908, the two cities of Reggio and Messina in southern Italy, were completely destroyed with a loss of life of approximately 200,000 souls. The more recent Italian earthquake of July 23, 1930, probably had its inception in the same region, which is an active seismic one, and had the proper precautionary measures been observed, the loss of life in both of these disasters would have been very greatly reduced. In general, the least risky part of the earthquake cycle is the period after a quake; while the stresses once more accumulate after several years. Yet, such is human nature, much attention is given to precautionary measures at the former part of the cycle, but the least at the later time of increasing risk.

THE greatest danger to the populace during an earthquake arises out of poorly constructed buildings and the tendency to become panicky. By referring to the accompanying figure, the danger to be expected from very high buildings becomes obvious. A high building during a shock may act as an inverted pendulum, so that a very slight oscillation of the ground will be greatly amplified in the upper portions of the structure. Notice a clock pendulum at the point of support. The arc through which it swings is slight. At the bob, however, the arc of swing is greatly amplified, and it is in this principle that the danger from high buildings lies.

In an active seismic region the heights of buildings should be, and frequently are, limited. The danger from falling cornices, high smoke stacks, and perched water tanks can not be stressed too much. In a metropolitan district, it is far safer to run into a Class A building than into the street during a tremor, as the greatest danger lies in falling objects rather than in collapse of walls. Buildings on filled or made ground, likewise are in more danger of collapse than similar buildings built on bed rock.

Movements are now under way, in many of the larger cities, to pass ordinances requiring that buildings be designed to withstand horizontal stresses as great as the stresses upon their foundations. Large buildings, dams, and similar structures should never be built over or close to a live fault, as the danger is imminent. Brick buildings, unless highly reinforced, should be avoided in active seismic regions.

The science of seismology is still in its infancy, so that it is difficult to predict just what strides in earthquake prognostication will be made within the next few years. It is certain, however, that at present, no person can predict the time of occurrence of an earthquake in advance. The old superstitions that earthquakes are more apt to occur during the summer in preference to other seasons, or that they are preceded by "earthquake-weather," is so much rubbish. No good can ever come of such fallacies. They should be relegated to oblivion with the old superstitions of witchcraft and astrology.



Multiple unit cars in service on the Illinois Central in Chicago. Passenger cars of this type are widely used in suburban and urban service

RAILROAD ELECTRIFICATION

By FRANCIS H. SHEPARD

Director of Heavy Traction, Westinghouse Electric and Manufacturing Company

WIDESPREAD opinion has it that automobiles, buses, and airplanes are taking the business of the railroads and that, therefore, they are being electrified for economy's sake. Neither the postulate nor the conclusion is correct. While railroads admittedly are not now operating on a high-profit basis, there is a steady increase in freight shipments and even an increase in long-distance rail travel and far-sighted authorities are very optimistic for the future. Economy has no place in the American scheme of electrification, for the operating economy on electrified American roads is practically nil. Mr. Shepard has, in the accompanying article, given us the truth, as an expert sees it, about rail transportation, its relation to the electrification problem, and the full significance of the latter—what it means to railroads, to the investor in railroad securities (who will read between the lines), and to the country at large.—*The Editor.*

RAILROAD electrification in the United States is entering into an era of increased activity. Several of our railroads are now beginning to electrify their main lines and others are actively considering plans to the same end. The cost of projects at present actually under way exceeds a hundred million dollars, and the total for those contemplated is many times that amount.

Much the same tendency is noticeable throughout the world. All of the nations listed in the accompanying table are either extending or planning to extend their electric service, and, in addition, electrification work is under way in seven or eight other countries.

No single cause is responsible for all this interest. Electricity as a tool for moving traffic has a number of advantages, some of which may be the determining factors in one case while totally different ones may govern in another.

IN many instances, especially outside the United States and Great Britain, the fuel situation provides the underlying motive for electrification. When a nation lacks abundant supplies of first-class coal but is favored with ample waterpower or some form of low-grade fuel, the use of electricity for railroad operation not only may effect a large saving in operating expenses but means independence of coal-producing countries in times of emergency. Switzerland, which has already electrified almost half of her route mileage, furnishes a typical example of this condition, and in the same category are Austria, Brazil, Chile, Italy, Norway, Sweden, and, to a lesser degree, France and Germany.

In this country, on the other hand, where the cost of coal and oil is comparatively low, little or no operating economy would result by saving fuel through electrification; the fixed charges of the electric installation would, in general, be greater than the cost of fuel saved. In the decision to carry out one American electrification—that of the Chicago, Milwaukee & St. Paul—the use of waterpower played an influential part, but all the other installations in the United States were due to other considerations, which can be summarized as follows:

Tunnels. The original application of

IMPORTANT ELECTRIFIED RAILROADS OF THE WORLD

	Electrified Route Mileage	*Total Route Mileage*
United States	2500	251,000
Argentina	68	23,000
Australia	230	22,300
Austria	450	4370
Brazil	251	18,700
Canada	40	40,000
Chile	210	5400
Cuba	155	3800
Czechoslovakia	30	8800
France	875	33,000
Germany	975	36,000
India	150	38,000
Italy	1070	12,000
Japan	200	13,000
Morocco	150	900
Norway	115	2000
Spain	370	9700
Sweden	730	9800
Switzerland	1550	3600
South Africa	200	11,800
United Kingdom	450	24,000

electric power for main line haulage was made in 1895 by the Baltimore and Ohio Railroad for the purpose of avoiding smoke conditions in its long tunnel under the city of Baltimore. The success of this undertaking and subsequent development led to the use of electricity by the New York Central, the New Haven, and the Pennsylvania railroads for their tunnels into New York City, by the Boston & Maine for the Hoosac Tunnel, by the Grand Trunk for the St. Clair Tunnel, and other installations.

SUBURBAN *and Terminal Service.* The development of the electric street railway and, especially, the use of electrically-operated trains on the elevated railways of Chicago and other cities, showed that electric operation was superior to steam in many respects for heavy suburban service. Electric motor-car, or "multiple-unit," trains accelerate more rapidly and hence can make better time than steam trains, even if the maximum speeds of both are the same; on running into a terminal they can be run out again without further switching, whereas several car movements are needed to reverse a locomotive-hauled train, which not only require time but may congest the tracks outside the terminal; they can run through residential districts without seriously affecting real estate values; and, of course, they can move freely in tunnels of any length.

For these reasons, electric operation was adopted by the Long Island and the New Haven railroads in the vicinity of New York, the Pennsylvania at Philadelphia, the Illinois Central at Chicago, and the railroads around London, Paris, Melbourne, and other large cities.

Mountain Grades. Of a group using electric operation for totally different reasons, the Virginian Railroad is typical. The chief business of this road is to haul coal from West Virginia to tidewater at Norfolk, Virginia. Its line crosses the Allegheny Mountains and at one point some very heavy grades against traffic are encountered. Under steam operation, these grades formed the "neck of the bottle" for the railroad. Even with the use of the most powerful of steam locomotives, traffic slowed down here and the capacity of this portion set the limit to the entire road.

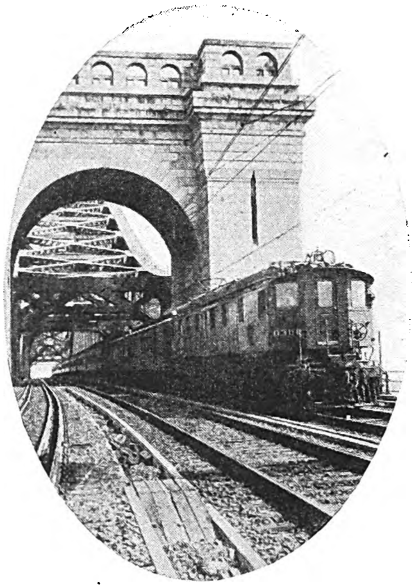
In order to increase this capacity, which was becoming more and more necessary, there were two alternatives: to retain steam operation and increase the number of tracks, or to increase the power for each train by using electricity. Owing to local conditions, the cost of additional tracks would have been exceedingly high, so electric operation was decided upon. Today, locomotives applying at times more than 20,000 horsepower per train are in use on this road, and trains are being moved up the steep grades at twice the former speed. The net result has been to increase the capacity of the road by more than 100 percent, with even greater capacity available if needed.

Other railroads using electric power for mountain-grade divisions include the Norfolk & Western and the Great Northern.

IT is obvious, however, that if these reasons alone influenced electrification in this country, we would see no general use of electric power here. The electrified areas would be confined to the great cities, the mountainous districts, and some special localities, but steam would be employed everywhere else. This, indeed, was the situation until very recently—until, in fact, the Pennsylvania Railroad announced its plans to electrify its entire system of all services from New York to Washington and as far west as the vicinity of Harrisburg, Pennsylvania.

In order to appreciate the full significance of this electrification, which is the most extensive and comprehensive one in the world, it must be considered in relation to our transportation situation as a whole.

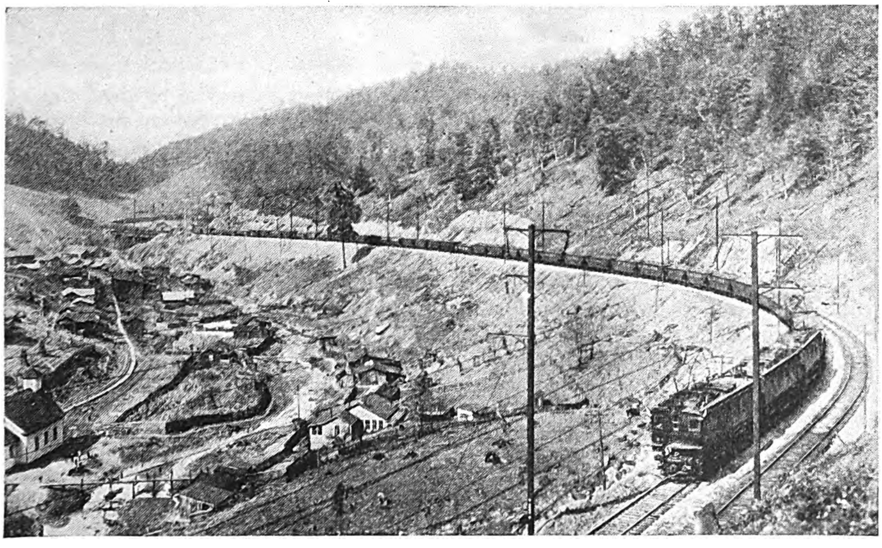
Railroad transportation is vital to the United States. Because of it, our vast territory has been developed and our people have been held together as a single nation. The moment our transportation service fails to meet our needs—as it did during and immediately following the war—everyone suffers: the price of everything we purchase and the cost of everything we produce promptly rise.



Crossing Hell Gate Bridge on the New Haven: The Colonial Express with its 178-ton electric locomotive

OUR demand for rail transportation far exceeds that of any other people. We require 4000 ton-miles per capita, whereas the British requirement is about 500 ton-miles. And this demand has shown marked growth: our ton-mileage for 1900 was 100,000,000,000, and today it is 440,000,000,000; and although with the present trend the aggregate is not increasing, this may be assumed to be only a temporary condition. It is true that a decrease in passenger movement has taken place recently due to the advent of the automobile, but this applies mainly to local and branch line service. On the other hand, there has been a pronounced increase of passengers traveling long distances and between populous centers. The automobile is, in fact, creating traffic by increasing the general movement of our people, by opening up areas for residence which were previously inaccessible, and by making us more travel- and speed-minded. The airplane is also acting in this same direction.

In spite of increase in the demands upon our transportation system, there has been practically no increase in the



A 6000-ton coal train on a 2 percent up grade of the Virginian Railroad, hauled by three 215-ton, 11,000 volt, single phase, Westinghouse-equipped power units

number of freight-train-miles or in the number of locomotives for the past 20 years. This means that our train units are becoming progressively heavier, and trains are being moved at higher speeds. The increase in ton-miles per hour has been nearly 50 percent in less than 10 years. The size of the locomotive has likewise grown, and the trend is conclusively toward more and more horsepower per train.

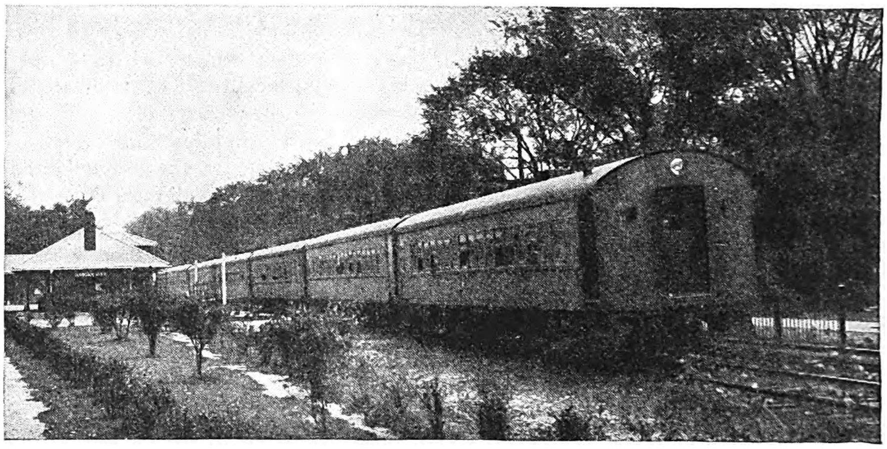
A crack silk train of the Chicago, Milwaukee, and St. Paul drawn by a 300-ton, 3000-volt direct current, Baldwin-Westinghouse electric passenger locomotive

Rail traffic, like automobile traffic, seeks those highways which are most advantageously situated. Half of our route miles carry about 90 percent of our traffic; while the great trunk lines, which constitute only about 10 percent of our route mileage, handle at least half the traffic. There is, therefore, an increasing pressure of traffic on these major routes which has been met by increasing the size and speed of the trains.

So far, the steam locomotive, which has recently undergone conspicuous and notable development, has kept pace with our needs and will continue for many years to be the mainstay for most railroad mileage; but there may be serious question if it can meet the demands of intensive trunk-line operation after the next 20 or 30 years. Double and even treble the present movement may conceivably be the requirement.

With electric operation, on the other hand, the amount of power that can be applied to each train is practically unrestricted, and electric trains of any size can be operated at any speed within the limits set by the road-bed, draw-bars, and other mechanical equipment. Hence, an electrified railroad has greater capacity than the same road under steam power. To electrify a rail highway is to broaden it.

Behind the great electrification undertaking of the Pennsylvania Railroad, therefore, may be seen a recognition of our future transportation needs, a vision of an unhampered and ever-expanding flow of traffic, and the desire to give the public the utmost in railroad service.



Multiple unit operation in heavy duty suburban passenger service on the Long Island Railroad. This is a familiar type of car in many metropolitan localities

Important also is the inauguration by the Reading Railroad of the electrification of its lines radiating from Philadelphia; and it is understood that ultimate extensions will be made for high speed and through service. Increasing interest is also being manifested by other railroads in electrifying sections of their main lines.

Parallel to the progress in developing the utility of railroad electrification, has gone on an evolution in the kind of electric power employed. All the early systems followed street railway practice and used direct current at 500 volts supplied by a third rail. In 1902, B. G. Lamme, Chief Engineer of the Westinghouse Company, announced the results of his experimental development, sponsored by George Westinghouse, of an alternating-current motor which could operate at all the various speeds and under the different conditions required by railway service. This announcement, which indicated the possibility of serving any track with a single working conductor at any desired voltage and of supplying power to trains in any desired amount, instantaneously and effectively, aroused world-wide interest.

In 1905, the New York, New Haven & Hartford, being governed by plans for future extension, adopted the new alternating-current system with overhead conductor at 11,000 volts. This method of operation has since been adopted and made standard by Norway, Sweden, Germany, Austria, and Switzerland, and, in this country, by the Grand Trunk St. Clair tunnel installation, the Hoosac Tunnel of the Boston & Maine, the Great Northern, Pennsylvania, Norfolk & Western, and the Virginian Railroad.

The success of the high-voltage overhead system of the New Haven stimulated the development of high-voltage direct-current equipment, and this current has been applied for various lines at 1200, 1500, 2400, and 3000 volts. Shortly after the war, the French Commission decided upon 1500 volts, direct current, as the official standard for France. The same system is in use in Japan, Java, Holland, and some other countries, while 3000 volts direct current is in use in South Africa, Chile, and Brazil, and by the Chicago, Milwaukee & St. Paul in this country.

The most extensive electrifications now being carried out in this country are with single-phase alternating current, as this system has greater promise for future advantage than any other.

ANOTHER PEKING SKULL DISCOVERED[1]

By PROFESSOR G. ELLIOT SMITH, F. R. S.

AT a meeting of the Geological Society of China in the last week of July, Prof. Davidson Black announced the discovery of another skull of Peking man.

In *Nature* of March 22, 1930[2], an account was given of the discovery of a series of remains of *Sinanthropus*, culminating in the recovery of an almost complete braincase by Mr. W. C. Pei on December 2, 1929, while clearing a sheltered recess of the main deposit at Chou Kou Tien. Some days before this skull was found, five human teeth were recovered from a spot higher up in the shaft, where they were associated with the skull of a large deer and some pieces of fossilised bone and blocks of stone, which were brought to the laboratory in Peking for examination.

This material was "developed" during the third week in June by the technical assistants working under Professor Davidson Black's supervision, and he found that there were enough fragments, which fitted together, to form the greater part of another uncrushed skull of *Sinanthropus*. He waited until the return to Peking of Dr. Wong (Wong Wen Hao), the Director of the Survey, before making the public announcement of his important discovery.

FOR reasons which are not yet clear to those who have not seen the actual specimens, Professor Davidson Black regards the skull found on December 2, 1929, as that of a young woman, and the calvaria, the discovery of which is now reported, is in his opinion that of a young adult male. It conforms to the same general type as the skull previously found, and its proportions are similar. But the braincase is not so thick and the frontal eminences not so pronounced. The most interesting new fact revealed in this discovery is the nature of the root of the nose, which is broad and flat, quite unlike that of Piltdown man.

The newly discovered skull was found in association with a number of teeth which can be assumed to have belonged to the same individual. This fact adds to the interest of two mandibles found in 1928 in association with the crushed parts of the respective braincases.

The remains of four skulls of *Sinanthropus* and teeth of at least six other individuals have so far been found. Thus there is available for study in China a much richer material of early Pleistocene man than the fragments of the individual specimens of *Pithecanthropus* and *Eoanthropus* provide. Moreover, the geological age of the Chinese fossils can be established with more certainty than that of the other two primitive genera, which are assumed to be roughly contemporaneous.

The fossils from Java and Sussex were found in gravels, where they had been deposited by running water. Although there is little doubt which of the heterogeneous fossils found in these gravels were contemporaneous with the human remains, in the case of the men of Peking, who left their bones in the cave where they lived, there is less room for doubt that the bones of animals deposited alongside them provide more certain data for the estimation of their geological age. Thus the claim made by Père Teilhard de Chardin and Dr. C. C. Young that *Sinanthropus* lived in Lower Pleistocene times rests upon a surer foundation than the similar claims that have been made in the cases of *Pithecanthropus* and *Eoanthropus*.

Further, the conditions under which the discoveries are being made at Chou Kou Tien hold out a greater promise of further evidence than in the cases where the fossils have been scattered by running water. Thus a series of fragments have already been recovered every autumn since the type tooth was recovered in 1927, and it is not unreasonable to expect that much more still remains to be found in this cave, and possibly in other fossil beds in the neighborhood. So far no worked tools have been found in the cave; but if such should be recovered, their association with the human remains will be less uncertain than in the case of the other Pleistocene men's implements.

FOR these reasons, in addition to the intrinsic interest and morphological significance of the skulls of *Sinanthropus*, the discoveries in China have an importance which is unique. It is a matter for congratulation that the investigation of this site should have fallen into such competent hands and that ample facilities and skilled assistance should be available for the work, which is being conducted with great thoroughness and insight.

HOW PLUTO'S ORBIT WAS FIGURED OUT

By **HENRY NORRIS RUSSELL, Ph. D.**

Chairman of the Department of Astronomy and Director of the Observatory at Princeton University
Research Associate of the Mount Wilson Observatory of the Carnegie Institution of Washington

NOW that the new planet has been detected upon photographs taken years ago we can be sure that we have a good idea of its orbit. But doubtless many people still are wondering why it took so long to be sure in what sort of path it was moving.

How astronomers can work out the orbit of a planet which they have been observing but a few weeks is a mystery to most people. Indeed we might go further, for even the graduate student of the science, who has gone through the long chapter of mathematical formulae to be found in treatises on the calculation of orbits and the still longer computations which actually apply them, has often no very clear idea of the *rationale* of the complicated process. He can not see the woods for the trees.

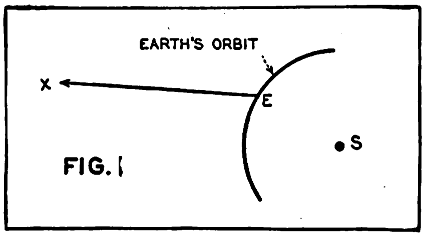

FIG. 1

Yet the thing is not really so hard to understand and, with due apologies to the reader whose tastes do not run along mathematical lines, let us for once consider the reader whose interests do, and try to explain as simply as possible how the apparently impossible thing is done.

FIRST of all we must realize what our planetary observations actually tell us. They give the apparent place of the body in the heavens among the stars; that is, each observation tells us very precisely in just what *direction* the planet lay from the earth (more precisely, from the particular spot on our planet where the observation was made) at an exactly specified moment. But an observation by itself tells us nothing at all about the planet's *distance.* Since the earth's motion about the sun can be accurately calculated we know just where it was at the time of observation (say at E in Figure 1). We can lay off this point on a diagram and also draw in the line EX which runs in the direction in which the planet was seen. (This line would usually run a little above or below the plane of the rest of the picture, but we may leave such details to the actual computer.)

But *where* is the planet upon this line? This is the main problem and it would be very difficult to solve if we did not know the laws according to which the planets move. Suppose that we have two observations, made at the time when the earth was at E_1 and E_2 (Figure 2). If the planet was standing still in space we could locate it at the intersection Y of the lines E_1X_1 and E_2X_2 on which it lay at these moments. But it was actually moving, and so can not have been at Y, wherever else it was.

NOW—to take a simple case first—suppose that the planet's orbit is a circle. We may then make any guess we please about its distance (say SR in Figure 2), draw a circle with this radius and find two points P_1 and P_2 at which the planet must have been if our guess was right. But *was* it right? We can test this by using Kepler's Third Law—that the squares of the periods of the planets are proportional to the cubes of their distances from the sun. We can find by measurement on our diagram, or far more accurately by calculation, what fraction the arc P_1P_2 is of the whole circumference. We know the time taken between these points and so can calculate what would be required to complete the whole orbit at this rate. If the result agrees with Kepler's law our guess was right. If not it was wrong and we try again with a new assumed distance SR′ and get two new positions P'_1 and P'_2. This time perhaps we find a motion slower than Kepler's law allows, whereas the first time it was too fast. The true value then lies between our two guesses and a few more tries will lead us step by step to the correct result.

Such calculations are often made in the case of a newly discovered asteroid to get a rough idea of its orbit and predict where it may be found a month or so later. Most of the characteristics of the general problem are well illustrated by this simple case. In the first place we see how the application of the law of motion turns an apparently hopeless problem into a very simple one. Secondly, we may note that a very small error in our observations may cause a serious one in our results. Suppose that we have got the direction of one of the lines, say E_2X_2, a little wrong. The distance P_1P_2 will then be wrong and, when we compute the time required to make the circuit of the whole orbit from that of this short arc, our error will be greatly magnified; and the same will be true of the final calculated distance. For this reason the computer must assure himself at the start that the observations which he uses have been made with skill and care before he wastes time on useless calculations.

AGAIN we may notice that our problem, as illustrated in Figure 2, admits of two solutions. Instead of starting with an assumed distance less than SY we might have adopted a greater one (SR″ in the figure). We would then have found the planet moving backward about the sun, but by the same process of trial and error we could have hit on an assumed distance at which the rate of motion would agree with Kepler's law. Two quite different planets, then, one relatively near the sun and moving forward, the other farther away and moving backward, each in a circular orbit, might both have been exactly on the observed lines at the correct dates. Later on, of course, their directions from the earth would differ and a third observation would tell which was the true answer (practically, since all of the thousand and more known planets move forward, no doubt would arise).

When the orbit is an ellipse (or a parabola or a hyperbola in the case of a comet) the problem of calculating it is much more complicated but the principles which have just been illustrated still hold good.

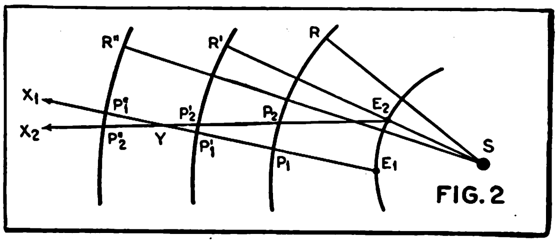

FIG. 2

In this case we must have three observations instead of two—which can be seen from very general considerations. If we have to find the values of a certain number of unknown quantities

—say six—we must have an equal number of equations (or, more generally, of known relations) from which to find them. No algebraical skill can get out the values of all six from only five independent data.

Now each observation of a planet gives us two such independent data, the right ascension and declination. To specify completely a circular orbit we require four "elements"—the node and inclination of the orbit plane, the planet's distance from the sun, and its position on the orbit at a given instant. Two complete observations giving four data to work on should therefore just suffice to work out a circular orbit; as they do. For an elliptic orbit there are two more elements to be found—the eccentricity and the longitude of perihelion, making six in all; and three observations will give us just what we need for a solution.

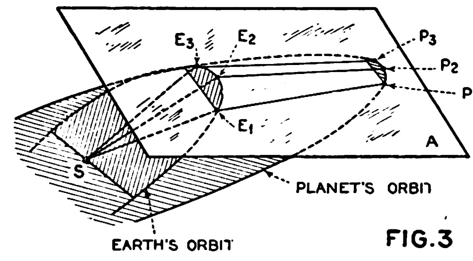

FIG.3

Once again the principal problem is to find the planet's distance. How it is done may best be explained by going back directly to the law of gravitation. We have now to take account of the fact that the orbits of the earth and the planet are in different planes both passing through the sun, as shown in Figure 3. $E_1E_2E_3$ and $P_1P_2P_3$ are the positions of the earth and planet at the three dates of observation. It is always possible to pass a plane A (the least shaded one in the figure) through the line E_1P_1 in such a way that E_3P_3 is parallel to it (though in the case represented lying higher) and E_3 and P_3 are at equal heights above the plane. Now the sun attracts both the earth and the planet, so that their orbits are curved and E_2 and P_2 lie higher than the other two points on each orbit. But since the earth is nearer the sun than the planet, the sun attracts it more strongly and curves its orbit more, so that E_2 will be farther from the one line than P_2 is from the other, and will be higher above the plane A than P_2 (the more so because the earth's orbit is more highly inclined to A than is the planet's). Hence the line E_2P_2 will not be parallel to A, but will slope downward and meet it at some point beyond P_2.

THE angle of this slope may be found from our observations, which tell us just where the three lines are—though not where the points P lie on them.

Now, making any convenient assumption about the distance E_2P_2, it is possible to calculate the influence of the sun's gravitation in curving the planet's orbit (that on the earth's is of course known) and hence to find what the slope of this line should be. Successive trials would then lead us to the correct value. When, as in practice, the arcs E_1E_3 and P_1P_3 are but small parts of the orbit it is possible to set up an algebraic equation which saves the time-consuming process of solution by trial and error and gives the desired distance directly. This equation is of the eighth degree but its solution has been made much easier by the calculation of special tables and presents no great trouble. When once the planet's distance at the time of one observation has been determined, its distances at the other two dates may be found by another equally simple application of the laws of motion under gravity (which, however, we have not space to describe in detail). To calculate the orbit about the sun is then easy enough. It may be noticed that, though the planet's orbit is drawn as an ellipse in the figure, the same reasoning would apply in the case of a hyperbolic comet. In fact the solution leads automatically to a determination of eccentricity of the orbit and the size and shape, whatever they may be.

ONCE again a small error in any of the observations is likely to be greatly multiplied in the results of the calculation. A "first orbit" based on all three observations is therefore usually of low accuracy. It serves completely, however, for predictions good enough to keep track of the planet until, some months after the discovery, it is lost to observation in the vicinity of the sun. Then by utilizing the data obtained in this interval a better orbit can be calculated, sufficient for finding the planet next year, and sometimes, as has recently been illustrated, on old photographs; and then a still better orbit may be calculated.

The general equation for finding the planet's distance has sometimes one real solution and sometimes three, leading to three different orbits in any of which a planet could move so as to be on the three given lines at the given instants. Charlier the distinguished Swedish astronomer has, however, shown that when a body is observed near opposition there can only be one solution of the problem and this is practically always the case for planetary discoveries. For a comet observed near the sun there may be three solutions, as happened for the great daylight comets of 1843, 1882, and 1910.

For a distant body like the new planet Pluto the apparent motion is slow and the effects of even very small observational errors may be considerable until observations covering several months are available. The delay in calculations and publishing an orbit of this most interesting body is therefore good evidence of the full comprehension which its discoverers had of the problem, as well as their excellent judgment.—

Cortina d' Ampezzo, Italy.

●

EDITOR'S NOTE: In the light of Professor Russell's lucid explanation of the standard method by which astronomers work out a new orbit, some notes on Pluto's orbit, by the astronomers Ernest Clare Bower and Fred L. Whipple of Lick Observatory, published in the August number of the *Publications of the Astronomical Society of the Pacific*, make interesting reading. These astronomers state that, between last January and June, more than 100 accurate observations of the orbital arc described by Pluto were made available by various astronomers, "but," they add, "these alone would not suffice were they not augmented by observations made possible by the identification of the object on plates taken before its discovery." This was because the January-June, 1930, observations would cover only about 1/500 of the full orbit—a pretty short arc from which to work out an accurate orbit. But at this juncture Mount Wilson, Yerkes and one other observatory came to the rescue with some old plates of the vintage of 1919, 1921 and 1927, which they had found in storage. With these "pre-discovery" observations the new arc now represented a span of 11 years or about 1/25 of the whole circumference of the orbit, a respectable base line from which to perform calculations. How closely Pluto now has been pinned down is shown by the fair agreement in the following results of various astronomers' calculations:

	By Bower and Whipple	By Nicholson and Mayall
Perihelion passage due	Feb. 27.473, 1989	June 5.5, 1988
Eccentricity of the orbit	0.253741	0.2575
Inclination of the orbit	17°8′57″	17° 09′
Period of revolution	249.1661 years	251.80 years

TELEVISION NEEDS NEW IDEAS—AND LESS BALLYHOO

The author

By A. DINSDALE, Assoc. I. R. E.

EVER since I reached the hospitable shores of the United States, nearly every person I have met has asked me: "Well, how long do *you* think it will be before we get television?" I never have felt any particular urge to assume the rôle of prophet, and it seems to me that prophesying about television is about as thankless a job as that possessed by the weather forecaster.

To begin with, it depends largely upon what you mean by television and what you expect it to do. In Europe the public, educated by a vast amount of advance publicity designed to boost somebody's over-enthusiastic claims, has acquired definite and rather high standards about television. It has heard so much about being able to "see the world from your own fireside," to watch the finish of the Derby or the final of the Cup Tie (England's star football match), that it expects just that. And as nobody so far is able to provide the necessary apparatus and service, the public has become somewhat apathetic. It has metaphorically rolled over and gone off to sleep again until something startling happens to wake it up. Extensive lecture tours have shown me that there is no lack of interest on the part of the British public, but much disappointment at the non-fulfilment of promises. "Hope deferred maketh the heart sick."

IN America the position seems to be rather more complicated. In the first place, there seems to have been even more ballyhoo about television over here than there has been in Europe. There are more people working on it, some earnestly and scientifically, and some not so scientifically, some with laudable aims, and some with aims not so laudable.

Since I arrived here I have talked with most of the leading workers in the field, and I can find no unanimity as to what television must be able to do. Dr. Alexanderson, for instance, thinks that a limited form of television will be sufficient, while Dr. Ives looks to the time when television will be able to do all that the talking movie can do, and as well. He contends, however, and I think quite rightly, that the system of television as developed by the Bell Telephone Laboratories for use in conjunction with the telephone, is quite adequate for the purpose. But that is a specialized application. The public expects broadcast television.

With television workers themselves at variance as to what television must be able to do, it is not surprising that the general public has no definite notions on the subject. At least, nobody seems to be able to tell exactly what the public wants or expects. Under these circumstances, the obvious thing to do would appear to be to give the public what you have, try to educate them into liking it, and keep on improving on it.

THAT television today is up against an impasse is a fact acknowledged by most authorities, although sporadic articles in the daily press would lead the layman to believe that television is soon to be ready for general use. This impression is fostered by interesting experiments on a laboratory scale which have been heralded as forerunners of practical home televisors. But even the best television equipment available today falls far short of the desired home radio-movie goal, and it becomes increasingly apparent that new paths must be beaten before present-day mechanical and electrical difficulties are overcome. The author of the accompanying article, formerly editor of *Television* (London), presents a point of view that is refreshing after the deluge of misleading publicity of the past few years.—*The Editor*.

The general public, however, will have none of the present limited form of television, which can show only a head-and-shoulder view of some distant speaker or singer, and that imperfectly. The fans, who love tinkering with something, have taken to it, of course, both here and in Europe, but commercial sets just cannot be sold. In England, the Baird Company's attempt to sell machines has met with but scant success. They blame the limited broadcast facilities granted them by the B.B.C.: 11 to 11:30 A.M. five days a week, and midnight to 12:30 A.M. two nights a week. But over here, where broadcast facilities are available on a more liberal scale, I am told that attempts to sell inadequate televisors are meeting with no better success.

The real reason for this failure is not far to seek, and is very simple. There is definitely no entertainment value in the present head-and-shoulder images. Realizing that fact, the Germans have made no attempt as yet to sell televisors; they are devoting all their energies to further experimenting.

THERE are some who disagree with me about the entertainment value of the present image, and point to the fact that something like 75 percent of a talking film is composed of close-ups. True, but the film shows more of the individual, more than one person at a time, has a lot more detail, and the producers have had years of experience with their medium of entertainment and have learned how to make it entertain. On the latter score the television people have reached the point where they say that "a new technique will have to be developed." Nobody knows yet just what form that technique will take. And at this stage they can not be expected to know.

Others who disagree with me contend that a start must be made somewhere, sometime, and point to the crudeness of the art of radio-telephony when sound broadcasting first started. It is difficult to compare two things which are totally different, but I believe that sound broadcasting, when it started, had more power to interest, entertain, and attract than has the art of television at the present time.

Just what the public expects of television is a question nobody can answer. Some go so far as to express doubt as to whether the public wants television at all! I think there can be no doubt that, after what it has been led to expect of television, any serious attempt to stampede the public into patronizing the present limited form of television will not only meet with failure, but will do the youthful art irreparable harm. Some harm has already been done.

Let us, therefore, survey the present state of the art from a technical angle. Let us create a standard of performance and see if present methods will permit of its achievement.

But let me make one thing clear before I proceed further. In reading over what I have written it would appear that I am a thorough pessimist, more of an enemy than a friend to television. Far from it. There is no doubt at all in my mind that television will ultimately arrive. It will eventually be able to do all that has been promised. Televisors will one day be as common in our homes as radio sets are today, and a television industry will grow to the proportions of the present radio industry.

But before all these things can happen we shall have to think up a few new ideas.

It is an extraordinary fact that television has not, so far, developed any brand new ideas for its own exclusive use. All its ideas and apparatus are either borrowed from some other field of scientific endeavor, or they have been in existence, but not made use of, for many years.

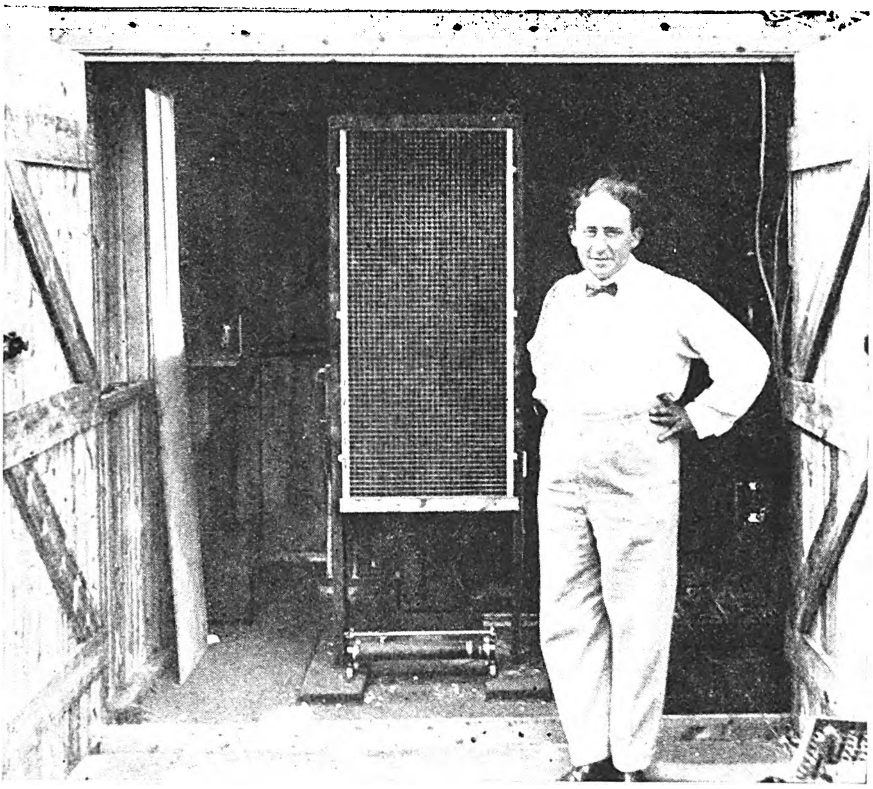
Take the scanning disk, for example. Invented by Nipkow in 1884, it lay idle until it was coupled with such modern inventions (taken from other fields) as the neon lamp, thermionic tube, and photo-electric cell, when television was produced. Nipkow could have done it in 1884 if he had had the use of these modern facilities.

THE large viewing screens of Jenkins, the Bell Telephone Laboratories, and Baird are reminiscent of the walls of selenium cells controlling distant electric bulbs, which were suggested by several early enthusiasts and actually constructed by Rignoux and Fournier in 1906.

The use of cathode-ray tubes was first suggested by Campbell Swinton in 1911, and they were experimented with soon after by Boris Rosing in Russia and Belin in France.

All these things have, of course, been vastly improved upon and made to perform incredibly well, thanks to modern facilities, but they have their limitations. What astonishes one is that all the present-known workers, knowing these limitations, are content to pursue the old methods. Some entirely new principle is needed, and needed badly. And it is quite on the cards that the present workers will get so stale and hide-bound that the new idea, when it does come along, will pop out suddenly and unexpectedly from a source never previously heard of.

Before we can proceed to an examination of the limitations of present television apparatus and methods, it is necessary to set forth some standard of achievement which must ultimately be met, and see how far toward that standard we can go with the means at present available.



Baird's large television receiving screen. The extreme complexity of devices of this nature is an important indication of the need for new ideas in the art

My guess is that television, for home entertainment purposes, will have to be capable of embracing a field of view, either indoors or outdoors, as extensive, complete, and flexible as is at present coverable by means of a motion picture camera, and the detail presented will have to be comparable with that of the motion picture also. After all, as an entertainment medium, television must go into direct competition with the motion picture, or couple up with it so that films can be distributed and simultaneously exhibited all over the country by television methods. It will displace the film for spot news, although the film will always be wanted for record purposes.

The home screen upon which the television images are depicted will have to be, for comfort and convenience, not smaller than nine by twelve inches, unmagnified. The magnifying lenses at present in use are undesirable for several reasons. Many of them are so badly designed and arranged that they distort the edges of the picture. Even if well arranged, they magnify all the defects in the image, cause loss of light, and, perhaps most important, limit the number of observers to two or three, and force even that number to locate themselves, often in discomfort, directly in front of the lens. The standard of comfort of the home movies must prevail on this point.

Having thus set the standards of field of view and size of screen, the next important step is to fix quantitatively the amount of detail which must be provided. Here it is necessary to guess a bit again. If scanning is to continue to be carried out in parallel strips or lines, my guess is that we shall have to provide 100 lines per inch. That means that, for a nine by twelve inch receiving screen, unmagnified, we shall have to resolve the image into $900 \times 1200 = 1{,}080{,}000$ picture elements. If we set the transmission speed at 15 images per second—a rather low figure—the frequency of the A. C. picture impulses which we must transmit, either by wire or by wireless, works out at

$$\frac{1{,}080{,}000 \times 15}{2} = 8{,}100{,}000 \text{ cycles,}$$

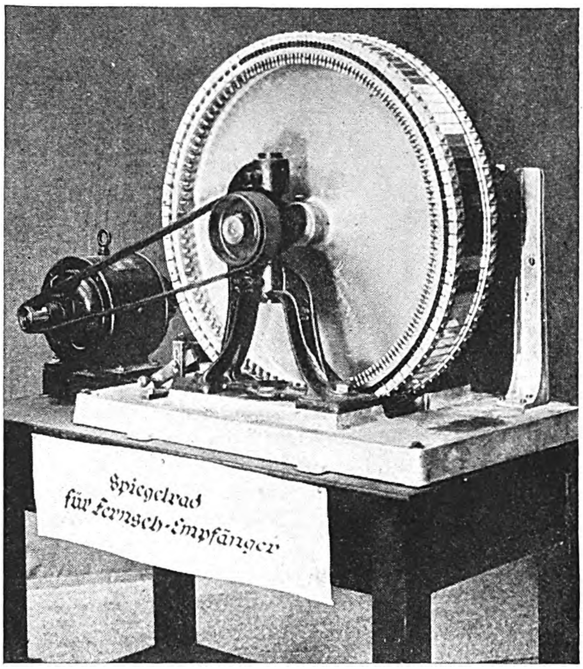
or 8100 kilocycles.

WE are now faced with two major problems: (1) terminal equipment capable of fulfilling the above requirements, and (2) channels of communication which will successfully transmit frequencies up to 8100 kilocycles.

Let us consider terminal equipment first. Remembering that the circumferential distance between the holes of a scanning disk must be equivalent to the long side of the picture, in this case twelve inches, and that there must be 900 of them, we should require a scanning disk nearly 300 feet in diameter to fulfill the requirements set out above! And if we used a flat plate neon tube, we should need one with a plate measuring slightly in excess of nine by twelve inches, and such a tube would require a prohibitive amount of amplifier power to illuminate it. The whole conception is preposterous and ridiculous.

The Jenkins drum scanner provides no solution to the problem; it also would assume unwieldy proportions. There remains the Weiller mirror drum, which would require 900 mirrors, and if these were only one inch wide the diameter of the drum would be something like 25 feet.

That exhausts all known mechanical methods of scanning which have proved at all successful. It is obvious, therefore, that we must either relax our requirements for television or seek other and non-mechanical methods.



The Weiller mirror wheel used in television scanning. For large images, this device becomes unsatisfactory

BEFORE the days of the thermionic tube, we achieved, or attempted to achieve, radio-telegraph communication by just such cumbersome "brute force" methods. Now we have thrown all our unwieldy machinery into the discard, and achieve our object a thousand times better by harnessing electrons. We shall have to discover some method of harnessing electrons to do our bidding in the television field. A stream of electrons travels with the speed of light, it is weightless and therefore inertialess, and it can be controlled electrostatically or magnetically.

The fundamental essence of the television problem may be defined as the time element, or, if you like, speed; so much has to be done in such a limited space of time. As we have already seen, 16,200,000 picture elements have to be dealt with *per second*. Obviously, only electrons are capable of handling such a gigantic number within the time allowed.

The only electron device at present known which seems to offer a ready solution to the problem is the cathode-ray tube. It has been experimented with for many years, and several workers are still busy on it, trying to adapt it for both transmission and reception purposes. As at present made and used, the cathode-ray tube has many disadvantages. It is expensive, both as to first cost and as to auxiliary equipment and operation, its life is short, and there are still difficulties in the way of adequately controlling the scanning movements of the electron stream. It remains to be seen, therefore, whether the cathode-ray tube is the best practical embodiment of the purely electronic method of achieving television.

So much for terminal equipment.

Coming now to channels of communication, one is almost tempted to say that it will never be possible to transmit 8100 kilocycles over either a wire or a radio circuit. But in scientific matters today's impossibility is tomorrow's commonplace achievement. At present it might be possible to transmit such an enormous frequency by radio, but only on wavelengths below ten meters. Obviously we shall have to discover some new technique or principle in radio communication also. That it is already long overdue is evidenced by the fact that the entire spectrum of wavelengths used for all radio communication purposes is already full to overflowing; radio communication cannot develop any further until it is released from its strait-jacket. Personally, I think the new principle discovered by Dr. J. Robinson of England, and incorporated in the Stenode Radiostat receiver, will not only solve the overcrowding problem but also make it possible to transmit the enormously high frequencies required for television.

That is my conception of the problem of television as it stands today. A gloomy picture, you may say. Or again you may ask me: "How long will it be—?" As I said at the outset, I am not going to be inveigled into prophesying, but I feel very optimistic about the future development of television. It is clear that much remains to be done, and it is equally clear that television is going to provide yet another example of the survival of the fittest. So much remains to be done that only those who are backed by almost unlimited resources in the shape of money, brains, and laboratory facilities stand any chance of winning through and reaping their reward.

The work which has been done to date, and about which there has been so much ballyhoo, must be regarded in the light of a preliminary canter over the course. Already there is evidence that the most serious contenders in the race for television are abandoning present methods and working quietly behind locked doors on something different. In Germany, Dr. Karolus, working in conjunction with the Telefunken Company, has been silent, but not inactive, for a year.

IN this country, the television staffs of the General Electric and Westinghouse companies have just been concentrated in the R. C. A.-Victor plant at Camden, New Jersey. That the R. C. A. group really means business is evidenced by the utterances of its executives, and if further evidence is required of the imminence of television on a really commercial and entertaining scale, there is the projected 250,000,000-dollar Rockefeller radio city which Merlin Hall Aylesworth, President of the National Broadcasting Company, says is to be built around television. It is estimated that this building will be ready in three years, and that is as near as I will go to prophesying when television will be ready to make its bow to the public, not in so perfect a form as I have outlined as being ultimately necessary, but at least some way towards it.

And finally, I have been asked who will win the race, Europe or America. Well, one of the essential qualifications of the competitors, mentioned above, has to do with financial resources, and America has more money to spend on television than has Europe, and America seems to be more determined. So with that I will leave the American workers to it, and wish them the best of luck.

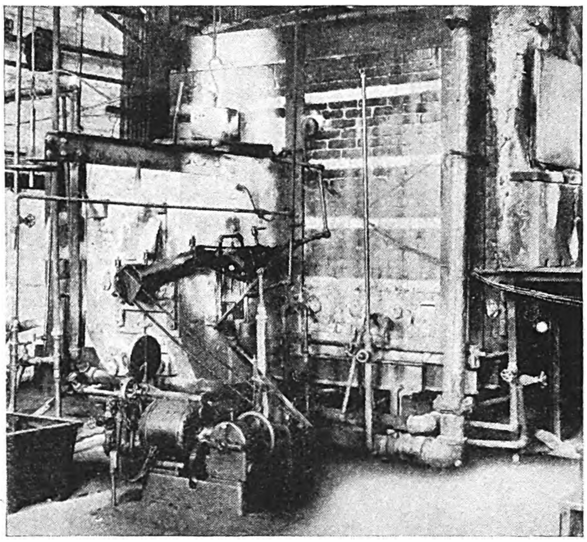
●

¶ *Editor's Note.* Although we are in hearty accord with Mr. Dinsdale in the general tenor of the foregoing article, we can not help but take exception to the statement ending at the top of this column. There are thousands of amateurs in this country who are learning the fundamentals of television by experimenting with their own equipment. And it is well known that the radio amateur is never content to follow the beaten paths. His record in the development of the short waves justifies this statement, and we do not feel that we are too optimistic when we express the opinion that the ranks of amateur radio will contribute some of the new ideas needed for the development of television.

GLASS TUBING BY THE MILE

THE old method of making glass tubing by blowing, while the hollow cylinder was pulled out and cooled, was an exceedingly crude process and the variations in the size of the bore were great. Now, however, by the aid of cleverly designed machinery, although under the principles of the archaic methods, glass tubing is made by the mile. The machines operate continuously, drawing the molten glass from the furnace, cooling it at a distant point and cutting it off in pre-determined lengths, automatically, by a special mechanical device. In this method, as in the hand process, there is a long line of easily broken tubing in constant motion between the blow-pipe and the far end where the cutting operation takes place.

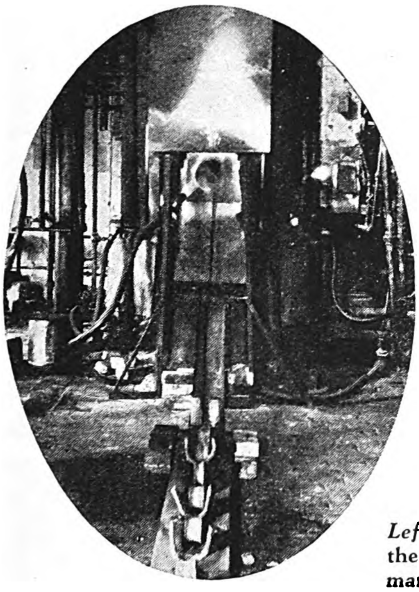
A tank furnace supplies a steady stream of molten glass. As the viscous glass flows to the aperture, it is kept very hot by the glass blow-pipes. The glass forms a tube over a hollow mandrel by the aid of air which is forced through it. The air pressure is slight, being only one or two ounces per square inch. If this air should be cut off, a cylinder of solid glass would form. After the tube is formed comes the drawing process which is dependent on a machine which pulls away, continuously, the rapidly cooling tubes of glass. Two endless chains serve to carry pressure plates which grip the tube without fracturing it. The motion is positive and in one direction. The cooled tube is drawn away from the furnace, dragging away more of the molten glass which is to form the tube over the hollow mandrel which purveys the air for blowing. The machine is dealing with a very peculiar substance and the slightest tendency to buckle up would fracture the tubing. The speed of the pulling chains may be adjusted at will.

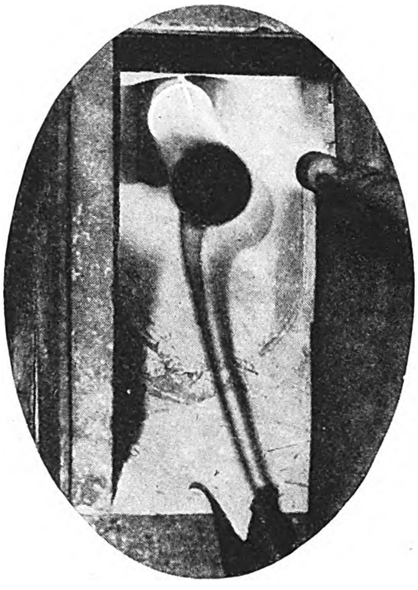


View of the rear of the glass melting furnace

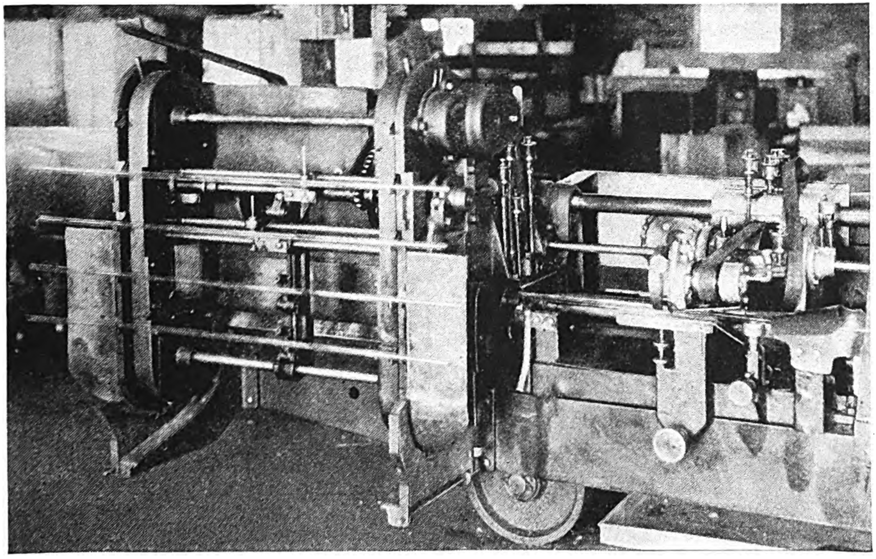
The pulling machine is supplemented by a device for breaking off the tube in pre-determined lengths as it is pulled along. After the tube leaves the endless chains it encounters a second set of guide-rolls mounted on vertical spindles. Next it passes over a pressure table which yields vertically. Then it enters a part of a special wheel and is broken off to the proper length. This length is finally delivered from the machine for inspection and packing. The cutter wheel co-acts with the pressure table. That is to say, the cutter wheel moves downward and comes into contact with the work at the beginning of its own stroke. The cutter wheel cuts a surface groove on the glass. It is not designed to effect a complete severance of the glass but to make a point of weakness. A second wheel revolves intermittently and exerts a transverse pressure against the work at a point in advance of the cut, thus breaking it off at the groove. The demands for uniform glass tubing, in science and industry, are many.

We are indebted to the Libbey Glass Manufacturing Company of Toledo, Ohio, for permission to inspect the interesting process.

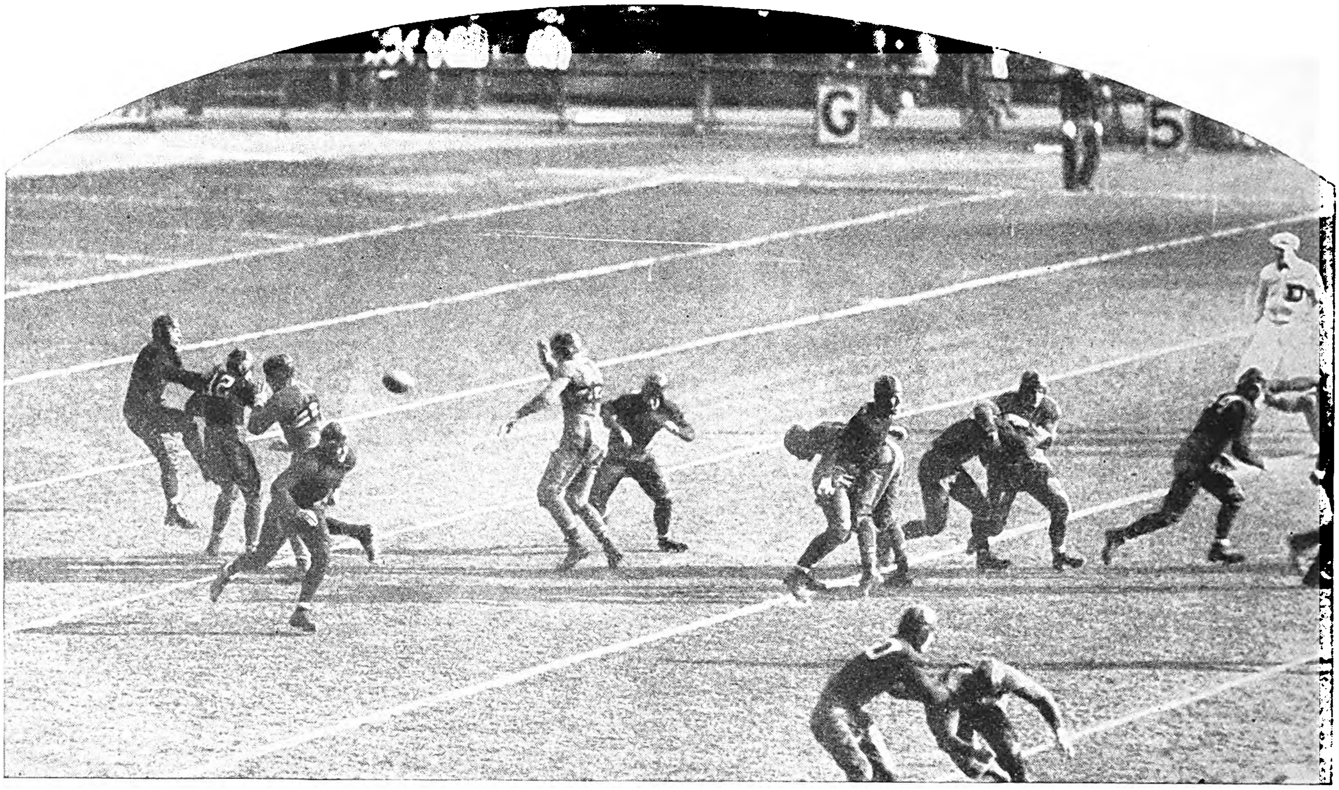




Left: Discharge end of blow pipe from which the glass is drawn. *Right:* Heater muffle and mandrel forming the continuous glass tube



After the glass tube has been drawn from the furnace with the aid of a "pulling" machine, it is cut off with this machine and the broken-off length is delivered



The Army blocks a Notre Dame punt in their famous 1929 game

HOW MANY MINUTES OF PLAY IN THE AVERAGE FOOTBALL GAME?

By HUGO L. RUSCH
Supervisor Technical Data Section, Johns-Mansville Corp.

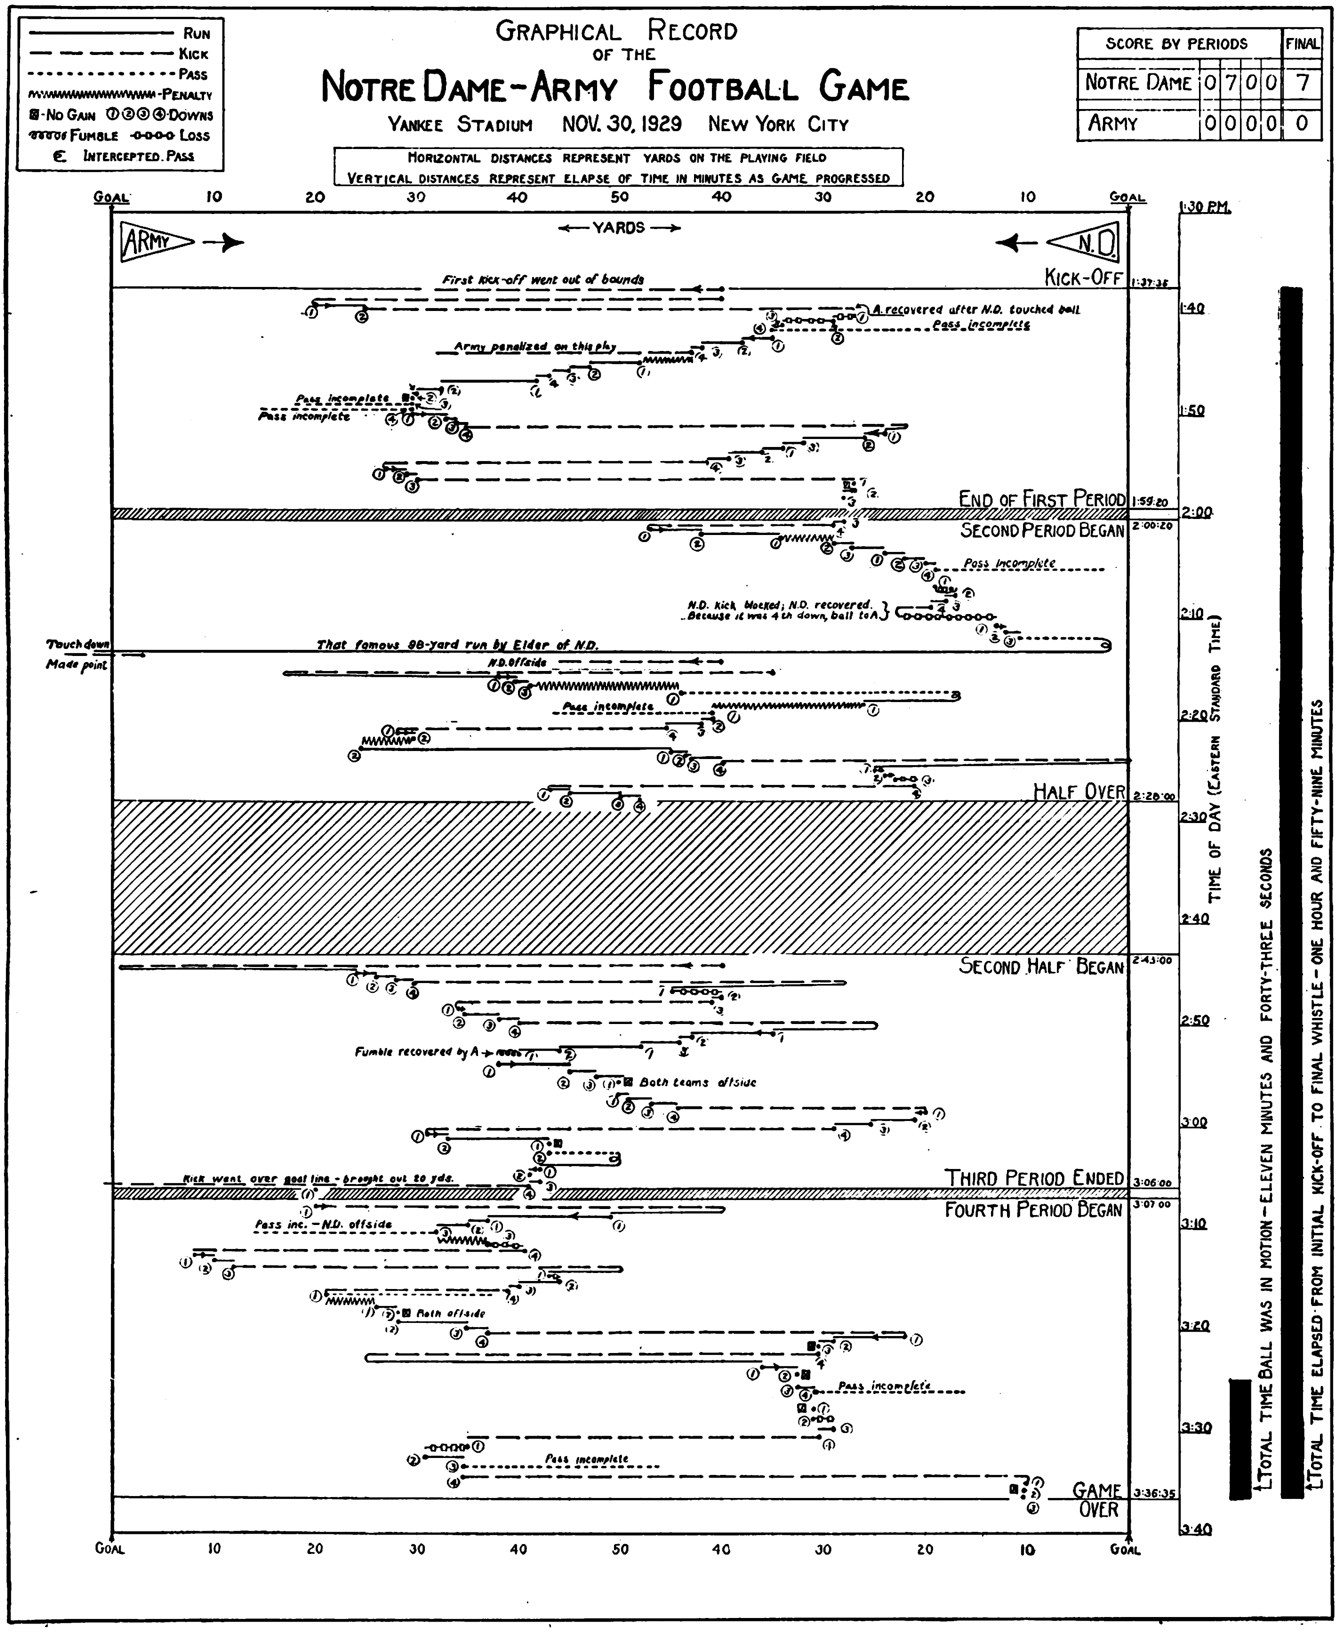
YOU pay at the rate of $24.25 per hour to watch football! It costs hundreds of thousands of spectators this amount for their amusement every autumn. The time the ball is officially in motion during an entire game—clocking each play with a stop-watch from the instant center snaps back the ball until the end of the play—totals the astoundingly short period of about 12 minutes. To be exact, the actual playing time in eight important games during the 1927, 1928, and 1929 seasons in which Notre Dame, the Army, Yale, Harvard, Princeton, Stanford, Ohio State, Columbia, Indiana, and Syracuse participated was an average of 12 minutes and 22 seconds per game. With your ticket costing you five dollars you paid at the rate of $24.25 per hour. If you were able to buy a ticket for three dollars, your hourly rate was only $14.55. If you were one of those spectators who paid sixty dollars a pair for the coveted pasteboards, figure out your own rate per hour.

The official playing time of one hour—four quarters of 15 minutes each—includes time for signals, formations, and shifts. The rest period between the first and second quarters, and the third and fourth quarters, is one minute; the time between halves is 15 minutes. Including periods for "time out," the total lapse of time from the initial kick-off to the final whistle, for the eight games mentioned, averaged 2 hours 20 minutes and 9 seconds.

TAKE the case of the Army-Notre Dame game at the Yankee Stadium on the last day of November, 1929—the game in which Elder of Notre Dame thrilled 83,000 spectators and many more thousands of radio listeners, when he intercepted one of Cagle's passes and ran 98 yards for a touchdown. For this game, many folk arrived half an hour before the kick-off and people were still leaving the stadium more than an hour after the final whistle, which blew 1 hour and 59 minutes after the kick-off. Hence some spectators spent about 3½ hours at the field to see the ball actually in motion less than 12 minutes (to be accurate, in this game it was 11 minutes and 43 seconds).

The time studies of the eight games proved that the period the ball is in motion during each play averages only 4½ seconds. This is based on a total of 1328 plays, all of which were carefully timed with a stop-watch reading to tenths of a second. As might be anticipated, some of the plays lasted four times as long as the average. And it was indeed apparent that the amount of spectator excitement was in proportion to the time the ball was actually in motion. The spontaneous cheers and yells were all concentrated in these very short intervals and all eyes were figuratively glued on the field.

On November 30, 1929, at the Yankee Stadium, in the second quarter, the Army had blocked one of Notre Dame's punts but Notre Dame recovered the ball. Since the play was on the fourth down, the ball went to the Army on Notre Dame's 13-yard line. Things looked fine for the Army. Two plunges by Cagle and Murrell netted a few yards, and then Cagle whisked a delayed pass over the left side of his line. Elder of Notre Dame rushed in boldly and, instead of playing orthodox football for a goal line defense and knocking the ball to the ground while covering receivers of the pass, he snatched



the ball from the air on his two-yard line, lost a precious split-second in regaining his balance, and then tore madly up the side line. Two Army men dove for him but missed—by a few inches. He ran unmolested until he reached the Army's eight-yard line when another West Pointer failed—by inches—to catch his elusive prey.

The fleet Elder raced over the goal line for a touchdown. But no one knew then that he carried the game with him. Carideo booted over a placement for the extra point, ending the scoring for the day. The crowd had been held spellbound. For 18½ seconds—the time of that play—they forgot the bitter cold. It was the longest play recorded in the eight games analyzed.

In the Army-Stanford game at the Yankee Stadium on December 1, 1928, there was another long play. Here also Cagle had a hand in it, but this time he did the carrying. The Army had the ball on their own 34-yard line. It was snapped back several yards to Cagle, who made a dazzling zig-zag run through the entire Stanford team, dodging tackler after tackler, to Stanford's 44-yard line for a net gain of 22 yards. It was a thriller. The play lasted 15½ seconds, the longest play of the game, and second longest in the eight games at which the time studies were made.

In the play which ranks third in point of time out of 1328, the performance of Christian Cagle of the Army is again encountered. This time it is in the Yale Bowl on October 22, 1927. With the ball on Yale's 48-yard line, Cagle received it about 12 yards back of the scrimmage line, and, by avoiding and throwing off Yale tacklers, down on his knees and back up again but never completely stopping, he carried the ball on another brilliant run of over 32 yards to Yale's 28-yard mark for a net gain of 20 yards. The total time of this play was 14½ seconds—14½ seconds bristling with thrills and gasps.

The average play in football—about 4½ seconds—hardly gives the spectators time enough to work up to a state of excitement. It remains for the long plays, such as the kind just described, to give the greatest thrills. It is these long plays that we like to see and read about. During each second of actual play the suspense is tremendous, and this is what really makes football the game it is for the spectators.

WITH the exception of the unusual plays such as those described, the punts consumed the greatest amount of time. They averaged about nine seconds, and the straight line plays three seconds. The average forward pass, counting those completed and also the incomplete, averaged about six seconds. The adoption of the pass has helped to spread the players more, and has served to increase the average time per play, thereby increasing the period of suspense and true excitement. Hence this change was a most important one from the spectator's standpoint—the standpoint that made half-million dollar gate receipts per game possible. Years ago the spectator saw little more than two struggling groups of 11 men each, pushing up and down the gridiron. The object was sufficiently apparent, but not the method of attainment. Consequently the game's power to draw paying spectators was not at its present height.

But what of the fact that the total time the ball is in motion during an entire game is only about 12 minutes? Shall we establish rules which will double or triple this period—the time during which the players are giving their every ounce of energy and the spectators are really getting the excitement they crave? No, it would not be wise to do so from either the spectators' or players' standpoint. Have you ever noticed that you are quite tired at the end of a football game, and particularly so if you are keenly interested in the outcome? As the ball moves back and forth on the field, you unconsciously push in the direction you would like to see the ball move. When the losing side cuts the air with "Hold 'em" they are unconsciously pressing their shoulders against an imaginary wall.

Students of public speaking and oratory tell us that a speaker who gets his audience extremely interested not only sways them mentally but also physically. It is said that the entire group of spectators at a football game actually moves with or against the ball, and by careful observation these waves of motion can be detected. Therefore, even though you may be paying at the rate of $24.25 per hour to see actual football, perhaps it is best for you that there is only 12 minutes of it. If you kept this tension steadily for an hour, you might have to be carried out of the stadium.

Cagle takes the ball

And now from the player's standpoint. A man running the 100-yard dash in 9-3/5 seconds is expending energy and moving at a rate which he could not maintain for 30 seconds. He would become so fatigued, if he tried it, that his pace would slacken before he traveled 300 yards. So it is on the gridiron. The men are giving every ounce they have, while a play is being executed, and it is undoubtedly good that the time per play *is* only a few seconds. Under the present rules, the players—all of them who have played hard—are usually nearly exhausted when the final whistle blows. The law of fatigue holds for everyone, regardless of his physique; the time for fatigue to take effect varies, of course, in the individual.

Consider the wear and tear upon human endurance during the game, when men line up for action 140 to 180 times. Little wonder that a rugged physique and heroic courage are required of the players. Hence it now can perhaps be better understood why, toward the end of a game, some of their performances are not quite up to standard.

Scientists tell us that when a muscle is stimulated, lactic acid is liberated in certain parts of the muscle. As this stimulation continues, an alkaline solution neutralizes the acid, which tends to relax the muscle. The process can continue until the available supply of alkali for neutralizing the acid is depleted. Then the excess acidity of the muscle stops its further activity and a state of complete exhaustion has been reached. Our whole voluntary muscular movement depends on this chemical reaction with lactic acid. There is a very definite limit to the extent any individual can use his muscles before complete exhaustion sets in.

The best way to win a mile run is to continue at a pace which will just produce exhaustion at the tape. If the pace is raised beyond this point, untimely exhaustion is certain to take place and the race is lost. Naturally, the longer the race the slower will be the average speed for each individual. Consequently, if the present rules and method of playing football results in near-exhaustion of the players at the end of the game, a change in the rules so there will be more actual playing time, without increasing the total time between the initial and final whistles, would mean a slackening of the speed and deftness with which each play is executed. Such a change would certainly not improve the game for the spectators.

A STUDY of the tabulated results of the eight games, with the number of plays and the time elapsed, provides some very interesting and instructive data. The number of plays per game averaged 166. The average number of plays per quarter varied between 40 and 43. This indicates that the proposed plan to play the game on the basis of 40 plays per quarter, in place of a definite time interval, will give us just as much football per game as at present. And, according to Mr. Harry R. Coffin of Harvard and other advocates of the new system, there are some very definite advantages. They claim the suggested period-by-play method has the following merits:

(1). It will eliminate the frantic use of the forward pass by the losing team during the final minutes of play.

(2). It will do away with any possibility of suspicious timing by officials.

(3). It will increase the interest of the spectators.

This system of playing was employed in the game between Brown University and Boston University in Providence on November 7, 1925, in which Brown won easily, 42 to 6. The consensus seemed to be that the score was too

A member of the *Scientific American* staff also visited Glozel, as did the author of the accompanying article, and made this and other photographs. According to one account the original "discovery" at Glozel was made while the young farmer, Emile Fradin, was plowing with cows. By chance, on the day of the visit, one of the Glozelians likewise was plowing with cows and within a few feet of the famous discovery site, which was at left just out of the picture

THE STORY OF GLOZEL—A CHAPTER IN CREDULITY[1]

By **DAVID RIESMAN**

Professor of Clinical Medicine, University of Pennsylvania

THOSE who have read something about Glozel may wonder why I speak of it here. Is it not a dead issue? No, for as a study of human credulity and as a commentary on the hot-headedness (or should I say pig-headedness?) of many men of science it will always occupy a prominent place in the history of civilization.

Although many are probably familiar with the main facts, I want to give a brief synopsis of the involved story. I say "story" advisedly for from the very outset the mystery of Glozel has formed a fascinating tale; very much in the genre of our best thrillers, with plot and counter-plot, gum-shoe detectives, and all the pertinent paraphernalia.

Glozel is a small hamlet of four farmhouses, about 15 miles from the famous French spa of Vichy. Emile Fradin, then a youth of 18 and belonging to an old local family, was one day working in his grandfather's field when a cow suddenly slipped into an unsuspected hole. Fradin went to investigate and found that the hole led into an oval pit containing a variety of remarkable objects—bricks, tablets, vases—which he gathered and as soon as possible showed to the village school mistress, Mlle. Picandet. The latter in turn showed some of the tablets to M. Clément, a school teacher in la Guillermie.

EVENTUALLY the news of the discoveries came to the ears of Dr. Albert Morlet, a surgeon of Vichy and an amateur archeologist. Thereafter Dr. Morlet and Emile Fradin together began to excavate at Glozel and brought to light more and more buried objects which they collected in grandfather Fradin's house and which Dr. Morlet described in detail in an endless series of articles in a literary journal, the *Mercure de France*. It was through this magazine—the *Atlantic Monthly* of France in more senses than one—that I became interested in the Glozelian discoveries. My interest was especially aroused by the claim of Morlet and others that an alphabet had been discovered at Glozel which antedated every other alphabet then known. I therefore decided while spending a vacation in the Auvergne to see Glozel for myself, but before doing so I determined to interview Dr. Morlet in Vichy.

At first he suspected me of being an archeologist but when in answer to a direct question, I denied the soft impeachment and proclaimed myself merely a doctor, he became cordiality itself and showed me his collection of Gallo-Roman and Glozel antiquities. He told me that he as well as others had been inclined to consider Glozel as belonging to the Magdalenian age because of the presence of harpoons and of stones engraved with reindeer and other animals long extinct in France, but further studies had led to the conclusion that Glozel was Neolithic. Dr. Morlet kindly asked me to

---

[1] Presented before the American Philosophical Society.

The little museum in the Fradin farmhouse. The crude sign mentioned by the author shows over the doorway. The picture was taken by a *Scientific American* staff member while perched on an "island" in the nearby manure-pile-quagmire, an entity which provides the cheery aspect from the typical French farmhouse. To see the exhibits he paid a few francs, as did the author of the accompanying article and, like him, was watched every instant by one of the Fradins; like a cat watching at a mouse-hole

stay over until the following day and dig with him and Professor Björn of Sweden, but I was unable to do so.

After leaving Morlet I motored, together with two American friends, to Glozel. Emile Fradin received us and at once offered to take us to the field of excavation. It was at the bottom of a deep ravine and was surrounded by a barbed wire fence. He showed us the original oval pit and the two tombs subsequently discovered. As it was raining hard and as the clayey ground was slippery, I declined his invitation to crawl into one of the tombs but asked instead to see the Museum. After paying two francs each we entered through a low door above which was a crude sign with the pretentious words, "Musée de Glozel," and found ourselves in a square low-ceilinged room with shelves on the walls and very primitive glass cases standing on the floor. The objects exhibited on shelves and in cases were astounding in number and variety—vases, tablets, engraved stones, ornaments (especially pendants), some pieces of glass, and harpoons, the last not nearly as artistic as those of Magdalenian age I had seen in Les Eyzies and at Laugerie-Basse.

Three articles attracted my special attention—vases or vase-like pottery ware having eyes, nose, and ears but no mouth, which Morlet has called death masks, explaining the absence of the mouth by assuming that the primitive makers wanted to express the silence of the grave. Secondly, a squarish object suggesting the female figure with a cylindrical projection from the forehead interpreted as the phallus—this Fradin told me was a bisexual idol; and most striking of all, clay tablets with graven signs looking in every way like alphabetical characters. I was struck by the clean red color of these tablets. When I spoke of this to Fradin, he explained it by saying that the soil in which the tablets had been found was such that it did not readily fuse with the clay and hence was easily brushed off. There were also some large casts of the human hand which differed from the imprints of the hands in the Spanish and French caves in having all the fingers present.

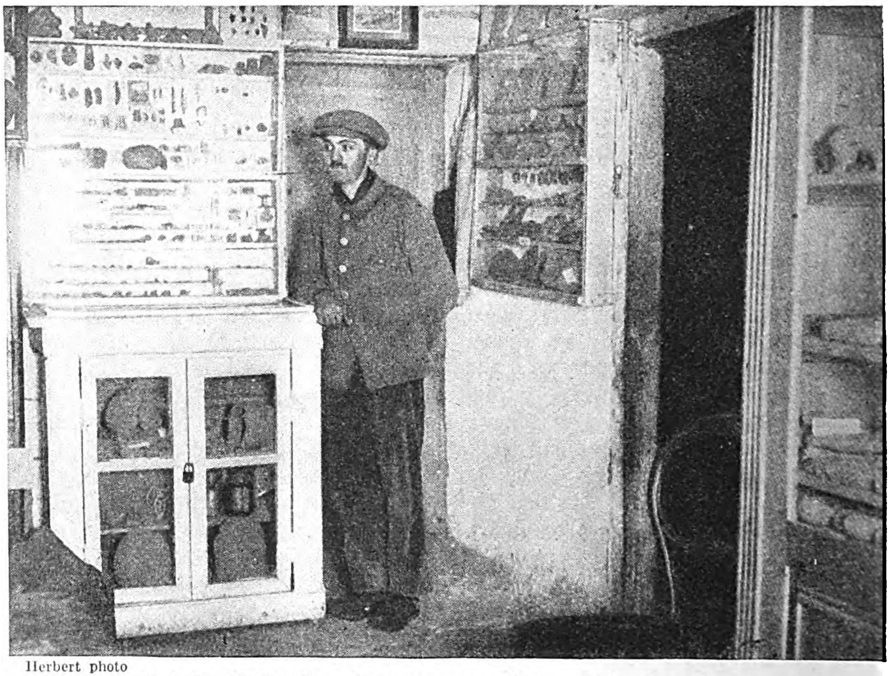
I offered to buy some of the articles, especially a tablet, but Fradin resolutely refused to sell. During the whole of our stay in the Museum, the grandfather stood silent and motionless in a doorway leading to an inner room.

The reputed discoveries of an alphabet dating back to Neolithic times, of which I had now seen the alleged evidence in abundance, created a tremendous sensation in informed circles. Altogether about 136 characters had been distinguished, representing every letter of the alphabet except the letter B.

Hitherto the credit for creating an alphabet had been given to the Phoenicians but the oldest known Phoenician record, found at Byblos a few years previous, dated back only to about 1300 B.C.; Sir Arthur Evens' baffling Cretan inscriptions to about 3000 B.C. If Morlet and those who agreed with him were right, then Glozel was truly what M. Reinach called it—one of the greatest archeological discoveries of all time.

ALMOST immediately after the first appearance of Morlet's reports, doubts began to be voiced about the authenticity of Glozel, though in the early period of the controversy there were perhaps as many scientists who accepted the discoveries in good faith as there were doubters. Soon the pro- and anti-Glozelians became personal and attacked each other with a vituperative vehemence and a destructive sarcasm for which the French language appears to be the ideal medium. Reputations were shattered, old friendships broken, and as one of the French dailies remarked—even butcher boys came to blows on the streets of Paris. In fact Mrs. O'Leary's cow did no greater damage to Chicago than Fradin's to the reputation of some French savants.

Before long the leading French pre-



Herbert photo

The principal, Emile Fradin, about 21 years of age at the time the site was investigated by the Committee. Although a humble peasant he had done better than average in school; he also was artistic and had done water color paintings. Perhaps it was a coincidence that the Glozel forgeries improved in technique from time to time as the schoolmaster Clément loaned Emile different pieces of literature on prehistory. The output of discoveries also corresponded with books given him by other interested dupes; it even accommodated itself in nature to the hopes and objections they expressed. Oddly, all periods of prehistory were represented by the objects discovered, from the Old Stone Age to historic times, and it is another coincidence that the illustrated textbook of prehistory in Fradin's possession covered the same scope. Picture taken in the museum historians with only an occasional exception began to deny the authenticity of Glozel and to declare the excavated articles to be forgeries. A number of Englishmen were likewise unconvinced. However, Dr. Foat, a London scientist, makes the categorical statement that "if the finds of Glozel are not authentic, it is equally necessary to consider as false all that I have seen in museums between London and Constantinople." Several Scandinavian, Belgian, and Portuguese scientists also supported Dr. Morlet, and a German, Dr. Wilke, in a recent article enthusiastically upholds the standard of Glozel.

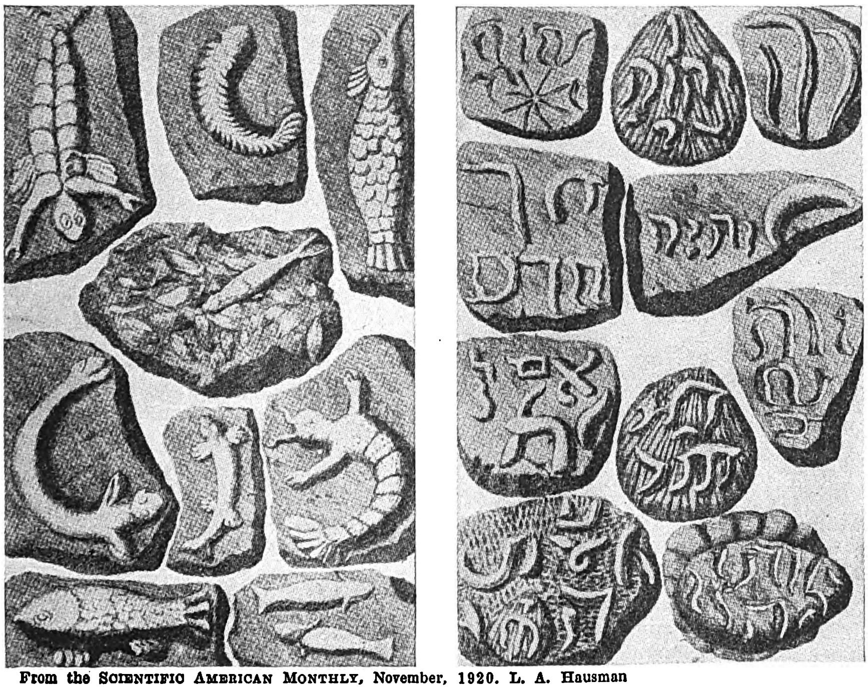
SCIENTIFIC AMERICAN staff photo

The actual site of the famous finds, at the lower end of a steep field above the valley of the Vareille stream. An attractive setting. The barbed wire fence around the site shows in the picture. It is easy for the tourist to reach Glozel; one goes to Vichy, where there are fine hotels, and hires a car to nearby Glozel

ARE Dr. Morlet's supporters right or is Glozel but one more of the long series of frauds that history recounts since Jacob imposed upon his father Isaac? Many will come to your minds—Thomas Chatterton, our own Dr. Cook, Constantine Simonides, the pretended author of the *Codex Sinaiticus*, the forger of the Mecklenburg Declaration, the Lincoln love letters in the *Atlantic Monthly*, the Tiara of Saitapharnes, and countless others.

One of the most interesting cases and the one having the greatest analogy to Glozel, if Glozel be a fake, is that of the so-called "Figured Stones of Würzburg." In the first half of the 18th Century there lived in Würzburg, in Bavaria, an ultra-pious physician named Johann Bartholomaeus Adam Beringer. He is not remembered for any great discovery or contribution to science, but for his share in a remarkable scientific hoax. At the time in which Beringer flourished an active discussion was going on as to the source and meaning of fossils. Although Leonardo da Vinci had understood their true nature—even Herodotus, 400 B.C. had a correct idea—the scientists of 200 years ago accounted for them as the result of "stone-making forces" of "formative qualities" or as growths from seeds. We may be inclined to smile, but with Dayton in Tennessee to chasten us, we can not throw stones at the Würzburg of two centuries ago nor at the Sorbonne which a hundred years later deprived the great Buffon of his chair because of his heterodox theories.

Beringer had committed himself publicly to the belief that fossils were the capricious fabrication of God, hidden by Him in the earth for some inscrutable purpose. His zealous maintenance of this fundamentalist position led some of the students, together with members of the faculty and wags of the town, to make numerous "fossils" of clay which they buried in the side of a hill where they knew the Professor was wont to search for specimens. Beringer, chancing upon these objects, was completely deceived. The jokers became bolder and buried the most extraordinary and extravagant figures their whimsical imagination could suggest. They fashioned tablets bearing inscriptions in Hebrew, Babylonian, Syriac, and Arabic, and buried them not far from the original spot. Beringer was overjoyed to find such abundant confirmation of his doctrines and forthwith in true German fashion proceeded to write an exhaustive treatise.



From the SCIENTIFIC AMERICAN MONTHLY, November, 1920. L. A. Hausman

Some of the famous Beringer fakes

THE wags now began to realize that they had gone too far. They expostulated with him and even told him the whole truth. Instead of believing them Beringer became more than ever convinced that the story his frightened colleagues told him was a ruse to rob him of the honor of his discoveries. No one could stop him. At great expense he published in 1728 the "Lithographiae Wirceburgenses."

Only too soon the shout of laughter with which the book was greeted brought the truth home to him. In chagrin and despair he exhausted nearly his entire fortune in a fruitless endeavor to suppress the edition and to buy up the copies already issued. He died soon afterwards, it is said, of a broken heart.

Is Dr. Morlet, like Johann Beringer, the victim of deception? Upon me personally he made the impression of an honest man. In certain quarters he was accused of fraud, for example, by the "Journal des Debats" and by the French Society of Prehistory. He promptly brought suit against them and won a

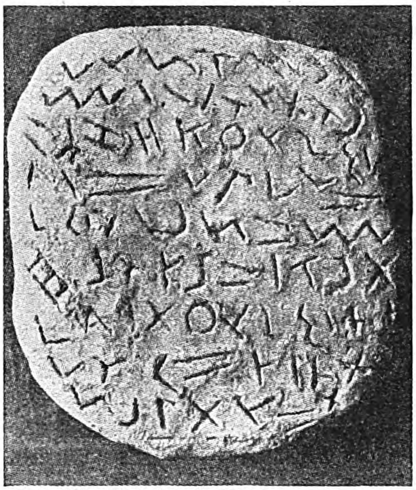
Exhibits in the museum of Glozel. Some are pots having eyes, nose, and ears but no mouth, as Dr. Riesman relates in his article. The "idol" to which he refers may be seen. Most of the objects in this picture are of pottery but the other finds have a wide variety— engravings on bone and stone, chipped flint and bone artifacts, and so on, representing a prodigious amount of industry on the part of (?)

verdict of 1000 francs damages. The defendants carried the case to the Court of Appeals at Riom, the native town of Willa Cather's lovable archbishop. In confirming the verdict, the Court gave expression to an amusing quibble. It held that Morlet, being a surgeon by profession and only by avocation a prehistorian, was not injured in the eyes of his real colleagues but only as an amateur archeologist. But as the defendants had not actually proved fraud, they were declared guilty though the fine was reduced to one franc and costs.

ANOTHER humorous episode might be mentioned. Regnault, President of the French Society of Prehistory, sued a Monsieur X because he, Regnault, had been compelled to pay the sum of four francs to see a collection of fake objects. As part of this legal action, the police of Moulins broke into Fradin's premises and took away a number of objects which were afterwards submitted to the public expert, M. Bayle. The latter reported that the tablets were of recent manufacture. Pieces of clay from a tablet crumbled readily in water; hence it was not conceivable that the tablets could have resisted the moisture in the ground had they been there for many years. Furthermore, a bit of grass picked out of a piece of earthenware showed under the microscope the vegetable cells, and some of the bone instruments still contained marrow. Bayle was soon afterward shot to death by one Philopponet against whom he had testified in court.

The Fradins themselves brought suit against M. Dussaud, member of the Institute, who in a trenchant brochure had called them fakers.

Let us now delve a little more deeply into this mystery so that we may understand better the basis of the controversy. The first serious doubt as to the authenticity of Glozel was based on the heterogeneity of the articles in Fradin's museum. How could one explain the presence of so many disimilar and unrelated objects—the 2000 or 3000 at the time of my visit have now grown into 5000 in one small field of excavation. No other archeologic site offers a parallel.



From "Glozel" by Dr. A. Morlet

One of the many inscribed tablets. After a fancied resemblance to the old Phoenician alphabet was mentioned the subsequent "discoveries" oddly came more and more to resemble Phoenician. Later, M. Bayle, the "Sherlock Holmes" of France, found minute strands of cotton colored by aniline dye in one of the clay objects. Perhaps, however, the apologists for the Glozel incident would say this proved that Neolithic man of Europe (5000 to 11,000 years ago) understood the synthetic chemistry of dyes

Morlet answered this by saying that Glozel was a *Champ des Morts*, a cemetery; and that, as among many primitive peoples of later times, everything belonging to the dead had been buried with him. C. Jullian, who considers Glozel a Gallo-Roman station, accounts for the multiplicity of objects by the assumption that Glozel was a sorcerer's sanctuary. He has added greatly to the gaiety of nations by attempting a full translation of the inscribed tablets from the published illustrations. Dr. Morlet showed me with much amusement a crack in one of the tablets which Jullian had translated as a character.

Aside from the puzzling complexity of the collection, it has been pointed out that the tablets first exhumed bore fewer and less perfect characters than the later ones. Further, as soon as some one had made a criticism, the objects next exhumed were free from the criticized defect. Quite often certain features appeared that could be traced directly to scientific articles published shortly before. These facts seem, of course, very significant. Moreover, the scratches on stones, whether representing animal figures or alphabetic characters, were without the patina covering other parts of the stones, suggesting a recent production. Much was made of the penetration of roots into vases or tablets; but upon examination these roots were not found to be properly fossilized, which would have to be the case had the objects been in the ground for long ages. The utensils—harpoons, hand axes, scrapers—are far less artistic than those in other Neolithic stations. Vayson de Pradenne and Abbé Breuil indeed contend that none of them could ever have been used.

DR. MORLET and his chief supporter Van Gennep did their best to answer all these objections. The former at the height of the verbal battle-royal made a request for a governmental commission which was speedily granted, but when he found that a bitter anti-Glozelian, the well-known archeologist Capitan was a member, he objected and the Commission was never sent. Eventually, at the International Anthropological Congress at Amsterdam an International Commission was formally appointed to investigate Glozel. The Commission consisted of Absolon, Director of the Archeological Museum of the State of Moravia; Bosch Gimpera, Professor in the University and Director of the archeological work of Barcelona; the Abbé Favret; Forrer, Director of the Prehistoric and of the Gallo-Roman Museum at Strassburg, Miss Dorothy Garrod, Member of the Royal Anthropological Institute and of the French Prehistoric Society; Hamal-Nandrin, Lecturer on Prehistory in the Museum of Liège; Peyrony, Director of the Museum of Les Eyzies; and Pittard, Professor of Anthropology in the University of Geneva. Absolon was prevented from taking part in the work of the Commission.

After spending three days at the site the Commission issued a unanimous report which was kindly sent to me by Miss Dorothy Garrod. This report states unequivocally that the articles are for the most part of recent manufacture and have undoubtedly been planted in the ground by some one whom the Commission does not name; and that Glozel is neither prehistoric nor authentic. Vayson de Pradenne in a devastating brochure in which he declared the Glozel finds fakes, also accused no one by name but put the blame upon the "Esprit de Glozel;" in other words upon a fairy.

ONE might think that with the leading French, English, and American scientists—Peyrony, Pradenne, Abbé Breuil, Sir Arthur Evans, Dussaud, and, I believe, Professor MacCurdy—arrayed against Glozel, and with the destructive judgment of the International Commission, Glozel would cease from troubling the scientific and the lay mind. Though all due obsequies have been performed, Glozel refuses to remain in its sepulchre, and the literary battle continues. Dr. Morlet constantly sends me newspapers and pamphlets[2] and a distinguished pro-Glozelian of Belgium, Professor Tricot-Royer, has just supplied me with his defense of Glozel which is particularly interesting because Professor Tricot-Royer was present during the visit of the International Commission.

What keeps Glozel alive? First we have the fact that when men take sides in print they are loathe to recant, fearing ridicule—the more untenable their position, the more stubborn their resistance.

Secondly, six months after the International Commission's visit Dr. Morlet called together a Comite d'Etudes consisting of Dr. Foat, Bayet, and Tricot-Royer of Belgium, Reinach, J. Loth, W. Loth, Van Gennep, Deperet, Ajcelin, Roman, Audollent of France, and Soderman of Sweden; all sympathetic to Glozel. At their meeting they pronounced unanimously in favor of its genuineness.

Another reason is found in the attitude of a group of French and German scientists who are opposed to the traditional belief that *ex oriente lux*—that civilization is of oriental origin. The alleged Neolithic alphabet of Glozel and similar finds at Alvao in Portugal are grist to their mill.

In addition quasi-political factors have entered into the controversy—Fradin an obscure peasant, Morlet a provincial doctor without much influence, have a definite appeal for the proletariat and for a large section of the press.

And finally, it must be remembered that the Academicians are not always right—that they ridiculed Pasteur and Boucher des Perthes; and even Koch and Lister met a similar fate in the beginning.

All these elements co-operate to keep the spark of life in Glozel. Within the past few weeks the publication of an exhaustive treatise by Dr. Morlet has been announced.[3] This, however, I fear, can throw no new light upon the subject.

As a detective tale the story of Glozel remains unfinished and will remain so until a Sherlock Holmes discovers the person or persons who manufactured the articles and put them in the ground. What was his motive? How are we to explain the extraordinary industry that has fashioned 5000 or more articles, and how is it that he, the "Esprit de Glozel," escaped detection in a community of 29 souls where everyone knows everyone else's business. Or how, if there are witnesses to the dark deed, can we explain an unbroken neighborly silence extending over a period of six exciting years?

Dr. Morlet demonstrating his claims at the site, before the members of the "International Commission" of investigation. Vayson de Pradenne, president of the Prehistoric Society of France, in *Antiquity*, characterises him thus: "Still young and endowed with wild energy, with an inflexible resolution and a naïve and immoderate self-esteem; devoid on the other hand of competence and of the critical faculty, he threw himself whole heartedly into the fray"

---

[2] Similarly, the enthusiastic Dr. Morlet has sent clippings, newspapers, and pamphlets, and his publisher a book by the doctor, to a member of the *Scientific American* staff who, when passing through Vichy, attempted to see him, but who was given to understand by some one within the Morlet household that the doctor was seeing no one, and who left his card. Residents of Vichy suggested that the doctor was finding it expedient to "hide out" at the time, until the legal storm might blow over. —*The Editor*

[3] "Glozel," by Dr. A. Morlet, a copiously illustrated work published by Georges Desgrandchamps, 23 rue Boissonade, Paris (XIV^e). The especially interested reader will find a 20-page article entitled "The Glozel Forgeries," by A. Vayson de Pradenne, President of the Prehistoric Society of France, in the journal *Antiquity* (Gloucester, England), Volume 4, No. 14. Several *Cahiers de Glozel*, some by Dr. Morlet in his own defense, have been published by Paul Catin, 3 rue Sabot, Paris (VI^e); other matter, by Octave Belin, 26 rue Pasteur. —*The Editor*

BY-PRODUCTS FROM INDUSTRIAL WASTES

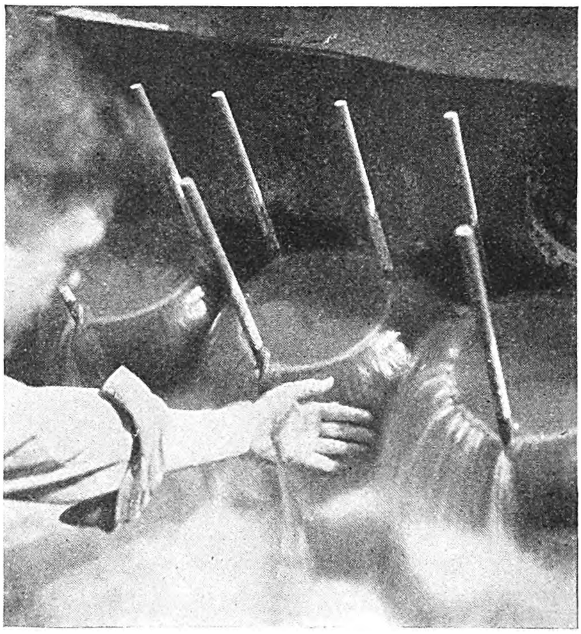
By ERNEST W. STEEL
Professor, Municipal and Sanitary Engineering,
Agricultural and Mechanical College of Texas

A STATE legislator not long ago seriously advocated the abolition of the state health department, and by inference all health departments, on the ground that at best they were wasters of public funds and nuisances. Persons of the same opinion may be surprised to learn that the complaints of health officials have stimulated industries to reclaiming large amounts of valuable materials which were wasting unheeded into streams and municipal sewage.

The liquid wastes of many industries are of such a nature that they cause serious troubles in streams and at municipal sewage treatment plants. In the streams, fish are killed and the water is made unsuitable for water supplies and recreational uses. At the sewage treatment plants, the biological action may be upset by antiseptic substances, or the enormous volumes of organic matter from the industry may overload the plant to such an extent that it must be increased in capacity or must by-pass untreated liquid into streams. Accordingly, many industries have in the past few years been notified by cities and state health departments that the burden of waste treatment must be assumed by the industry, either completely or in large part, before final discharge into sewers or streams is permitted.

SUCH notices have been received with apprehension by the industries concerned until study of the problem showed that what appeared to be a liability was capable of returning profits. An example of this is the Corn Products Refining Company of Argo, Illinois, which manufactures starch and other corn products. Final disposal of its liquid wastes is a matter of much concern to the Chicago Sanitary District. The chemists of the District found that the wastes of this plant were so large in volume and contained so much organic matter that they were equivalent to the sewage of a population of 800,000. The treatment of this waste was, of course, too great a burden to place upon the taxpayers. The alternative appeared to be the construction by the company of a special treatment plant, estimated to cost 2,900,000 dollars.

Investigation of the plant with respect to sources of the waste indicated that a considerable portion of valuable product was escaping into the waste pipes through poor control of certain processes. Improved mechanical equipment and weeding out of heedless operators remedied this. Result: a 10 percent decrease of the waste, and an increased output.



Clear overflow from equipment that reclaims an appreciable amount of wood fiber from the discharge water in a paper plant. Where this is not in use, the discharged water pollutes streams and kills fish

The greater portion of the waste, however, was composed of the liquor in which the corn is first steeped and softened. By installing comparatively inexpensive equipment the steep-water can now be evaporated to such a consistency that it can be used for making a stock feed. Result: an annual return of 500,000 dollars which was formerly lost through waste, and a reduction of volume and concentration of the plant waste from a population equivalent of 800,000 to about 50,000. The present wastes owe their strength to the organic matters distilled over in the vapors of the steep-water during the concentration process. It is possible that some valuable constituents can still be extracted, and further experimental work is being carried on.

Another industry which has frequently been embroiled with health departments is that of coke making. Coke is made by distilling coal, and many valuable products are in the distillate. After these are removed, there remains a liquid containing tar acids and phenol, or carbolic acid. The latter is especially troublesome, particularly if the stream or lake which receives the wastes is a source of municipal water supply within many miles of the point where the waste enters. If the water supply is chlorinated, the phenol taste is particularly bad. The disagreeable medicinal taste of the combined phenol and chlorine has been noticed when the water contained only 1/25 of an ounce of phenol to a million gallons of water. Methods of recovering phenol from the still-waters have been developed and now it is possible to extract it and obtain salable phenol in amounts sufficient to pay the cost of extraction.

THE phenol problem has also received much attention on the part of scientists of France, Denmark, and Germany to prevent pollution of the relatively small rivers of those countries. From their studies comes a new and startling solution. It has been found experimentally that if the phenol-containing liquid is applied to the soil, the injurious constituents are converted into ammoniacal compounds which can be utilized by soil bacteria and act as crop fertilizers. The conversion process takes about two weeks. Previous to the change, of course, the phenol is injurious to plant growth and accordingly the liquid must be applied a proper length of time before sowing. A very important advantage claimed is that, while the phenol is still active, it will destroy weeds and injurious insect larvae present in the soil. The combination of fertilization and weed and insect killing properties may change entirely our methods of disposing of this troublesome waste.

In the bituminous coal mining regions of the eastern states there have been many disputes between mine operators, cities, state health departments, and fish conservation commissions. The drainage water of coal mines contains little or no dissolved oxygen and hence will not support fish life. It will so lower the oxygen content of streams into which it discharges that fish cannot live in them. Mine wastes are even more troublesome because of the acid and other chemicals which they have dissolved out of the coal beds. Acid is a killer of fish and in addition makes the polluted streams black and evil smelling and unsuitable for municipal water supplies. The only remedy found so far has been to require owners of mines to seal up those abandoned workings from which drain water trickles down the hillsides. Lately, however, the Kaplan process is reported from West Virginia. It consists of adding to the mine waste a complex chemical which combines with the undesirable chemicals to form a useful blue pigment, which has a far greater value than has the chemical reagent added. Appropriately enough, the new pigment has been called Monongahela blue.

IN all of the forested states are mills engaged in turning wood into various grades of paper. The process requires much water—to break down or digest the wood into fiber, to wash it after digestion, and to convey the fiber around the plant through pipes and channels. Indiscriminate discharge of the wastes has changed streams which traverse regions of great scenic beauty into black and evil-smelling open sewers. Fish are destroyed. Regions which are ideal for camping, fishing, and vacationing are spoiled.

The paper industry, however, after exertion of much pressure by state health and game officials, is doing much to remedy the situation. Study of plants indicated that much of the conveyor water with its valuable fiber was escaping accidentally or through remediable carelessness. Some fiber unavoidably escapes from the paper machines. This waste is being reclaimed by special patented sedimentation processes which allow return to the plant of the rescued stock. At some plants the water, after removal of fiber, can be returned for further use. This is especially profitable where the water must be pumped long distances from the original supply or must be filtered or otherwise treated before it can be used.

The wastes from the digesters and washers contain much chemical matter that is especially undesirable in streams. The chemicals need not be lost, however, and most paper plants are now installing systems for evaporating this waste. After evaporation, the residue is burned and the chemical is regained in a modified form. The magnitude of this procedure is indicated by the fact that 7000 gallons of water must be evaporated for each ton of pulp manufactured.

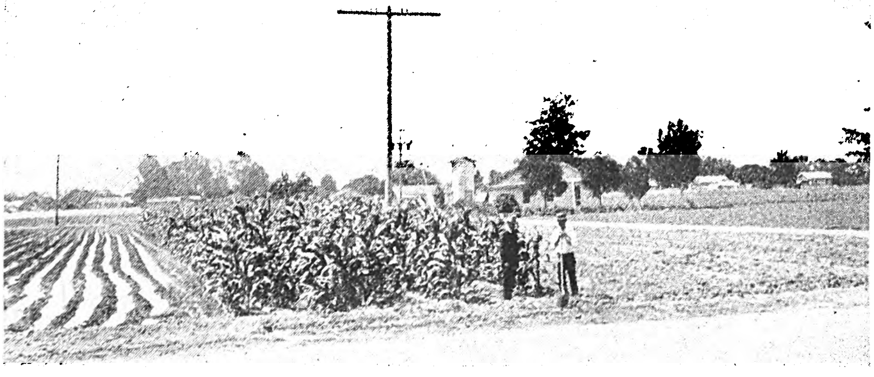
Most troublesome of all problems to the paper industry is the disposal of the highly corrosive liquid wastes from the sulfite pulping process. Some progress has been made by some plants which are converting the waste into adhesive and other by-products having commercial value. Experimentally, investigators have found that alcohol, road binders, linoleum cements, dyes, fertilizers, and many other products can be made. The difficulty is that sulfite waste is produced in such enormous quantities that if all of it were converted into by-products, the market probably could not absorb them all, although alcohol manufacturing may possibly be the final solution.

THE textile industries also produce troublesome liquid wastes. Foremost among these in difficulty of treatment is wool-scouring waste. It contains much dirt, wool fiber, and grease. Wool fibers can be caught on fine screens and returned to the plant. Grease is highly undesirable at sewage treatment plants, and wool-scouring establishments are required, or at least encouraged, to remove all grease before discharging wastes into sewers. After removing grit and heavy dirt, the waste is treated with sulfuric acid which changes the grease into a thick scum and sludge easily removable from the liquid. The scum and sludge are then pressed and the grease is squeezed out. The grease so obtained is very largely lanolin, which is much used as a base for medicinal ointments. The cake that is left behind after grease extraction has some value as a fertilizer.

The most frequently encountered waste is that from plants which handle milk or manufacture milk products. At sewage disposal plants, milk waste sours and upsets the normal bacterial action. Discharged directly into streams, the usual results of stream pollution, nauseous odors, and killing of fish follow. The whey from cheese-making plants is especially troublesome in this respect. Whey has been found to be a valuable hog food and is returned to farms for that purpose. The ordinary milk wastes contain much casein. It can be precipitated by small amounts of sulfuric acid and the resulting thick sludge fed to chickens or hogs. Since casein has many uses in the industries and can be converted into glue, or into poker chips and other artificial ivory objects, it is highly probable that the large condensed milk and cheese factories will eventually salvage this material.

IN spite of the progress which has already been made, stream pollution by industries is a rapidly growing problem. This is due not only to the increasing industrialization of the country but also to the tendency of industry toward decentralization. Formerly industries grouped in certain regions or in the large cities. Their wastes, together with the domestic sewage of the large concentrated population, were discharged into the large rivers, lakes, or harbors where centers of population naturally developed. Comparatively few bodies of water, therefore, were grossly polluted. Now, however, factories of all kinds are scattered over the country. Advantageous as this may be to the industry and to its employees it has been harmful to many streams.

Possible damages to streams should be a matter of concern to all industries contemplating relocation. Town and city officials who are tempted to bid eagerly for a new industry would do well to inquire into the nature of the wastes which it may unloose upon the countryside. Should deleterious wastes be features of the particular manufacturing process, an agreement as to their disposal may prevent unpleasantness. Finally, where wastes are already causing trouble, scientific inquiry, carried on by the industry in co-operation with the proper governmental authorities will probably bring about a solution to this problem, the growth of which is measured by the growth of industry.



Milk wastes discharged into streams cause harmful pollution. This photograph shows creamery wastes being used to irrigate a farm

THE YOUNG GIANT: NATURAL GAS FUEL*

THERE was a slight trembling as, 480 feet below the surface, the crude string of tools dropped into a pocket. The trembling became a dull rumbling, like distant thunder, and the rumbling a rapidly swelling roar until there burst from the mouth of the rough casing a mighty column of mud, oil, and water, borne on the driving fist of a tremendous pressure that rocketed tools and equipment high into the air.

The drillers cheered. At last, after two years of slow, plodding effort, they had struck oil. They were rich.

But their cheering was short-lived. The dark stream soon thinned out and then disappeared altogether, leaving only a colorless substance escaping into the air and a roaring noise that seemed to mock them. The well was a failure, it seemed, for they had struck, not oil, but a gas pocket.

For days the terrific pressure blasted millions of cubic feet of natural gas into the atmosphere in an ignorant waste that would make the gas producer of today weep, while the owners of the well stood around disconsolately and wondered if any oil would follow. Finally, after weeks of waiting, they gave up hope. Some months afterward the roaring gas jet was ignited and the towering torch lighted the countryside for miles around, symbol of a later day when natural gas would be burned for heat and power in home and industry.

THE above incident, which is typical of hundreds, probably, in the early boom days of the petroleum industry when oil was the gold men sought, actually took place at West Bloomfield, New York, in 1865.

As a matter of fact, natural gas is as old as petroleum in the experience of men. But because it was often practically invisible, ignorance shrouded this masquerading giant of power in a veil of superstition for many centuries. The ancient oracle of Delphi is said to have been situated near natural gas fissures. According to the story, a shepherd noticed that some of his goats wandered about queerly in a certain spot. Going over to investigate, he felt a certain lightness coming over him. Villagers came at his call and immediately experienced the same dizziness, talking in disjointed sentences. So they concluded that a god must live there who had cast a supernatural spell on the place, and accordingly built a temple on the spot.

The Chinese and Japanese may have been superstitious too, but apparently they didn't let their fears blind them to the useful nature of the product. Plenty of evidence has been found to show that these people burned natural gas and even transported it in crude lines made of bamboo or animal intestines. History is full of similar instances. But it was not until 1821 that the first gas well was sunk near a spring at Fredonia, New York—a good 38 years before Colonel Drake's historical oil well at Titusville. Like petroleum, however, gas had been discovered before while boring for salt.

Between superstition, ignorance, and, later, mechanical difficulties of production and transportation, it has taken man many centuries to tame the "wild spirit" of prehistoric times and put it to work for him. A natural gas pipeline map of the United States would show a connecting maze of gas lines in many parts of the country, yet not so very many years ago natural gas was only a by-product, a waste that had to be blown off sometimes before the oil came; or, at best, something that held the pressure which carried petroleum to the surface and saved a certain amount of pumping.

Natural gas operations represent literally an "industry within an industry." Yet the business of producing, transporting, storing, and marketing this

product differs widely from that of petroleum in many respects.

Consider production. In appearance, a gas field looks very much like an oil field to the layman. There are much the same derricks, tools, toolsheds, and pipelines. But the problem of pressure is much more vital in gas operations. The producer cannot put his well on the pump, as the oil man can, when the pressure fails. And the first well down in a new field, naturally enough, gets the full pent-up pressure of the entire area, which may be considerably reduced by the time other bits reach the gas-bearing sand. On the other hand, pressure is not always an indication of how prolific a field is likely to prove. Many an apparently promising area has come suddenly into being, yielded abundant stores for a year or more and then just as suddenly gone dead.

Just as difficult is the problem of transportation. Where the oil man can ship his product by pipe-line, tanker, tank car, by barge, in barrels, or in any other way that emergency may suggest, the gas producer has only one channel of transportation—pipe-lines.

ONE of the most perplexing problems, however, which the industry has had to face—one which has largely been solved by developments entirely without its sphere—has been that of marketing. As might be expected, the first use of natural gas was in the home. In areas within reasonable distance of producing fields, natural gas could be supplied cheaper, very often, than the manufactured product. But here the industry was up against the problem of seasonal demand. Inevitably, extremely cold days multiplied the drain on his pipe-line system eight to ten times. Just as surely, morning and evening drew heavily on the lines, with consumption comparatively slack during the day. Natural gas can not be manufactured as needed. If the supply is too great, the product must be kept in the ground. If it runs short, the producer has to find new fields if he expects to stay in business.

Let's see what the industry has done to get around these obstacles.

First of all, there is far less waste than in the old days. Seldom does one see gas blown wantonly into the air from wells sunk into strata containing both gas and oil. The former is far too useful for re-pressuring oil sands—to say nothing of its commercial value—to throw away. Next is the matter of storage. The producer today has found that by far the most efficient and economical method of storing his product is right in the ground from which it came.

A rugged ten miles of scenery on the Denver gas line. In distributing gas from the fields, pipe-lines must be laid across mountains and through rivers

It has been the widespread growth of industry and manufacturing, however, which in the last analysis has changed the whole outlook of natural gas markets, given the producer an incentive for seeking new and richer fields, and economically justified the huge capital expenditures for lines from producing areas to industrial centers.

The United States is the greatest manufacturing nation in the world. Nor are the factories and industrial plants of the country now crowded into the northern states, as they were in former years. Today industry thrives in the south and west where formerly cotton pickers crooned in the sun and cattle roamed the plains. The natural gas business was quick to realize that here was a chance for mutual development. Its new customer would consume gas in large quantities, and at a comparatively uniform rate throughout the year. In return, the industry could offer him the cleanest fuel known to science with a high heating value of approximately 1000 B.t.u. per cubic foot, one that burns completely with no smoke or ash.

It has been estimated that there are over four billion dollars invested in the United States today, in the various producing and marketing areas scattered over the map, with thousands of miles of trunk and feeder lines, like spider webs in a garret. The output of energy from natural gas burned in the United States during 1929 was estimated to be equivalent to 527 billion kilowatt hours—nearly six times the total production of electricity for the same period. Known fields, with improved methods of computing reserves, give the industry almost unlimited supplies of raw material to work with. Texas Panhandle and the Monroe-Richland field alone can assure the industrial markets of the south and middle west of adequate resources for many years to come. Yet all these assets of supply, scientific methods, and expanding markets which Nature, their own inventiveness, and evolving conditions have given the men engaged in natural gas operations, might well prove to be so many stones, yielding no profit, were it not for one thing. The industry has found to a remarkable extent the way to real practical co-operation.

The natural gas business is not a one-man job, so to speak. The product itself is easily susceptible of waste; and producing areas, unless scientifically drawn upon, may lose much gas that never reaches the market. The laying of lines from field to market involves the expenditure of millions of dollars. In distributing the product to numerous towns along the right of way, as well as at the destination of the main line, countless local interests have to be taken into consideration.

Here, then, is an invaluable natural resource. To bring it from its age-old prison, thousands of feet under the earth, to the burners of various industries in widely separated parts of the country, calls into play hundreds of varying interests. Producer, landowner, engineer, municipality, consumer, scores of others, all have their rights; all must be considered. The tiniest cog can wreck the whole machine.

So the tremendous projects which have been successfully swung by the natural gas industry speak volumes for the fine degree of co-operation, orderly exploitation, and scientific development within its ranks.

The eastern section of the United States was the cradle of the natural gas industry in America. From the producing fields in West Virginia, Pennsylvania, and east Ohio has crept a maze of pipe-lines carrying fuel to the scores of industrial centers throughout that territory, until the map takes on the appearance of a jig-saw puzzle. Today those eastern subsidiaries of the Standard Oil Company (N. J.) operate something like 16,000 miles of main and feeder lines, with estimated distribution for 1930 of 104 billion cubic feet of gas.

Yet, even before eastern markets for natural gas had developed to their present proportions, the wildest gambler would never have undertaken to pipe the product to Baton Rouge, St. Louis, or any of the great centers of the south or middle west. The industry would have laughed at him. And—at that stage of development—it would have been right. Production methods were not as scientific as they are today. Nor were the compressors and lines of a quarter century and more ago as efficient as they are today. Men had no way of estimating with any degree of accuracy the potential output of a field, and the industry could hardly be expected to gamble an investment which it would have to carry 10 or 20 years on the chance that the elusive material in the sands under their wells would last that long. Finally, many of the markets in the south and middle west were not yet ready for natural gas.

So fate played a fortunate trick on the industry in hiding from geologists the prolific Monroe-Richland and Panhandle fields until a time when the engineer and consumer had prepared the scene for more extended use of their treasures.

Panhandle is undoubtedly the greatest natural gas producing field in the world today, with the Monroe-Richland area not far behind. It is almost impossible to estimate how much gas lies locked in the sands of these two fields, needing now only the turn of a valve to release it. But a fair idea may be gained from the fact that the combined capacity of lines already tapping them runs up to several hundred million cubic feet daily.

Amarillo field alone, in the Panhandle district, was thought two years ago to hold some 10¼ trillion cubic feet—enough to keep a line of 100,000,000 cubic feet per day capacity operating continuously at full force for nearly 300 years. That this great natural wealth may be expected to last many years is plainly testified by the investments of many millions which have gone into the construction of 300-, 400-, and 500-mile lines.

There are three main projects through the south and southwest in which Standard Oil Company (N. J.) subsidiaries have an interest, the most recent being the Mississippi River Fuel Corporation's 431-mile line from Monroe to St. Louis. In addition to the main line, branches will make the gas available to industrial plants in Crystal City, Missouri; and in East St. Louis, Granite City, and Alton, Illinois. Other industrial consumers within reach of the main line through Louisiana, Arkansas, and Missouri also will be served.

In 1927, the Interstate Natural Gas Company completed its line from Monroe to Baton Rouge. The Interstate also contracts to furnish gas from its Monroe reserves for the Southern Natural Gas Corporation's line to Birmingham, Alabama; Atlanta, Georgia; and various adjacent points, as well as to several other interests. Over in Texas the Canadian River Gas Company transports the fuel from Amarillo Field, in the Texas Panhandle district, to Clayton, New Mexico. Here it is purchased by the Colorado Interstate Gas Company (N. J.), and brought to Pueblo and Denver, Colorado, as well as to other towns along the way. In addition, the Colorado Interstate supplies gas for a line north from Denver to Fort Collins.

And so the natural gas industry has grown. Once a "wild spirit," represented by mysterious pillars of fire that issued from fissures in the earth to terrorize natives, then an incidental by-product of oil drilling, natural gas today not only has found its way into homes in many districts, but more and more is replacing its brothers, fuel oil and coal, for numerous industrial purposes. Glass, ceramic and cement plants, steel mills, brick, lead, enamel ware and vitrified clay manufacturers, oil refineries, power plants, and all other industrial users within reach of existing or projected lines are giving ample illustration of the value of the product.

To what extent new producing areas, further improvements in drilling and transporting technique, and the possibility of mixing natural with manufactured gas for maximum economic usefulness in larger centers may justify extending the web of pipe-lines to other parts of the country, plans already announced and others in formation will reveal in the next few years.

Back to the primitive. In swampy land such as this, oxen and mules have proved to be about the best motive power for transporting pipes for the pipe lines

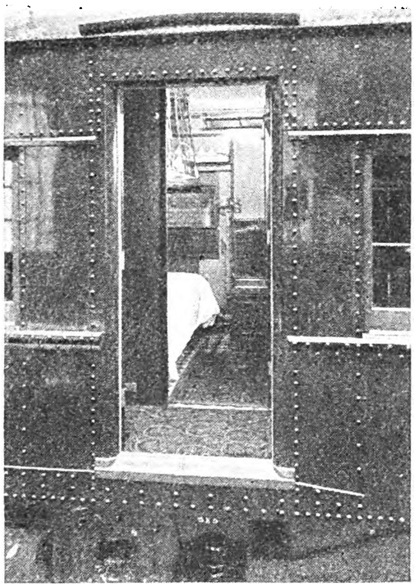
Invalids to or from the Mayo Clinic at Rochester, Minnesota, may ride in comfort in this special car

THE SICK MAY RIDE IN PULLMANS

THERE have recently been built, for operation on the Chicago and Northwestern Railway, two Pullman cars specially designed for the comfortable transportation of invalids. These cars will be operated between Chicago and Rochester, Minnesota, home of the famous Mayo Clinic.

Besides the regular platform entrances at the car ends, three doors are placed on one side of each car for the direct entrance of stretchers. These special doorways are 30 inches wide and two of them are so located that a patient on a stretcher may be carried directly into the room he is to occupy; the third provides access to the open-section division of the car. The rooms thus reached are extra wide, and provided with extra wide doors, so that the transfer from stretcher to bed can be made with the least discomfort to the patient.

Each car contains eight open sections, one drawing room, and four rooms; each room having a stationary single bed and an upper berth, as well as folding lavatory arrangements. The upper berth is available for occupancy by an attendant. At the section end of the cars is the lavatory for men, while that for women is at the opposite end.



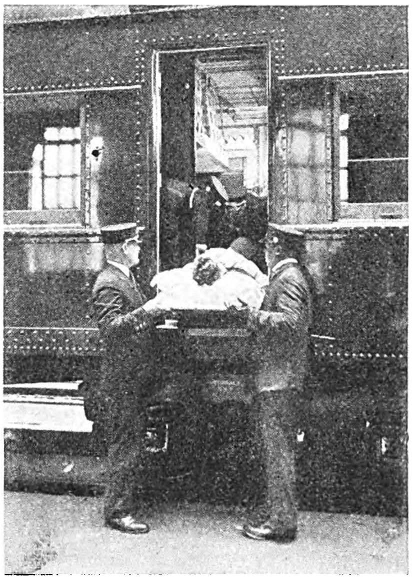
The side door, 30 inches wide, gives access to one of the private rooms

Particular attention has been given in the construction to eliminating as much as possible the noise of travel. Diaphragms at the car ends are spring-hung from the top, the arrangement greatly reducing the amount of car-end rattle. Further, rubber insets have been placed between car trucks and bodies at points of contact, to absorb shock and further reduce noise. The cars are also equipped with roller bearings.

Of invalids who require to travel, the proportion who are entirely bed-ridden is small; nevertheless a considerable number are either bed-ridden or require support in getting about; for these latter a short stretcher, really a canvas seat, 30 inches long, has been devised. This stretcher can be easily handled on entering or leaving the car, because the corridors have been widened for the special purpose of accommodating them. In the ordinary car it has often been necessary to remove a window sash in order to permit a person on a stretcher to be lifted in or out.

The third side-wall door, for patients whose space is in an open section, opens into the crosswise corridor which separates the men's lavatory from the aisle between the sections. Thus only one turn has to be made in carrying the patient in or out, and the use of the platform door and vestibule is avoided.

In a number of other details these cars have been arranged to accommodate this special service; for example, electric heating pads are provided. The cars were designed under the supervision of Dr. Thos. R. Crowder, Director of the Department of Sanitation and Surgery of the Pullman Company. They are appropriately named the *Ephraim McDowell* and the *Joseph Lister*, in honor of two men whose contributions to surgical science have been particularly notable. Ephraim McDowell was not only a country doctor, but a country doctor of pioneering days; he practiced in and about Danville, Kentucky, and there, in 1809, successfully performed the first major abdominal operation ever undertaken, for the removal of an ovarian tumor. There in the backwoods, before the days of anesthesia, unassisted, and with only the crudest of facilities, his boldness and skill combined to bring success in an operation of a type which, now commonplace, has since been the means of saving uncounted lives. Dr. Joseph Lister was the English surgeon who discovered and developed the principles of antisepsis.



The loading and unloading of invalid passengers bound for the Mayo Hospital is rendered easy by the side doors which permit the direct transfer of the patient on a stretcher to the car

THE TECHNICIAN TALKS ABOUT THE TALKIES

By RAYMOND FRANCIS YATES

SINCE the silence of the silent drama has been so effectively—or shall we say devastatingly?—broken, much has been said pro and con concerning this new magic of the movies. It must be confessed that, as measured by the box office receipts, "talkies" have, within the startling space of two years, emerged from the state of an uncertain experiment into that of a bombastic success. How deserved this success has been from a purely artistic or esthetic viewpoint, or how lasting it will be is a matter of some conjecture even at this late stage of development. This much may be said, however. The movie makers have, by sheer luck, struck upon a ready-made, ready-to-use idea that has revitalized the whole industry and captivated a public that is still applauding with enthusiasm.

As large as the success of this new idea has been there are many dissenting votes and much disillusionment on the part of movie goers who want their drama on the hoof, and who demand something more dramatically and emotionally substantial than heated bedroom scenes and voices that sound as though they might be produced when noses are clamped with clothes pins. In short, the talkies have not been universally successful and the possibilities of reaching this point will become more and more remote unless our movie manufacturers see more quickly their folly in attempting to produce pictures to meet the fickle demand rather than a standard of artistic perfection. We have seen and heard the talkies in their unpolished nakedness, and now we want stark realism with a ring of real sincerity back of it.

THE movie manufacturers have still much to learn of technical control of sound recording. To put a bald record of voice or music on the sound track of a film or the wax of a record is one thing. To give that record the expansive breath and verve of life is quite another thing. Even a superficial observer of talkie technique cannot help but lament the obvious absence of realism that is so noticeable in the average production. Contrary to what appears to be the established opinion of the critics, the fault does not lie wholly in the technical limitations of the electrical equipment but partly in its manipulation. To draw an analogy: the movie makers are playing a Stradivarius with the technique of a fiddler at a barn dance. In their frantic effort to please a fickle public and to take advantage of a demand that has swept down upon them with unprecedented fury, they have failed to tap the resources of their equipment.

Situated between the microphone in the set and the recording apparatus there is what is known as a mixing panel. Here the monitor listens-in on all sounds passing over the circuit on their way to the wax and photographic film records. This vigil of the monitor is of vast importance for it is he who regulates the degree and intensity of the sound-laden currents passing over the circuit on their way to the "canning factory." The monitor is lord over all that he hears; he may by a twist of his wrist make a whisper out of a call for help, or he may on the other hand make a cough sound like an eruption of Mt. Vesuvius. It is all in the knobs!

At present it is the monitor who is the weak link in the chain. He is all technician when he should be part technician and part artist. He is interested largely in microamperes and the response curves of audio-frequency transformers when esthetic effects and realism should be uppermost in his mind.

SOME months ago the writer was seated in the studio theater of one of our largest producers, reviewing bits of a musical comedy that had recently been filmed. The novices present talked with a learned air about the "highs" and "lows" of the recording, at the same time being serenely insensible to the appallingly bad job of monitoring that had been done in recording the sound. There was a close-up of a young lady engaged in a normal conversation with a friend. While talking, this young lady turned her back to the audience, but there was no change whatsoever in the intensity of her voice. Here the simple turn of a knob might have added a valuable touch of realism for it is obvious that orientation has a pronounced effect upon the voice. During conversation, turning the head affects the volume of the sound reaching the ear of the listener. A small effect, to be sure, but not small enough to lose every vestige of importance. It is going to be through the painstaking attention to these small effects that the movies will eventually emerge into a state of polished and formal art. The paramount question is,

THE motion picture, and now the motion picture in its talkie form, has become such an integral part of the average person's daily life, that any suggestions for improvement take on a personal interest. In the accompanying article Mr. Yates points out some of the failings of the talkies, and how they may be overcome. His technical background in sound work gives the voice of authority to his statements.—*The Editor.*

"When will the talkies learn to talk?" The answer lies with the technicians whose esthetic sense is usually no keener or more susceptible than that of a coal-wagon driver or an ice-man. It is a far cry from the grid bias of a vacuum tube to the artistic niceties that will eventually put more interest in faithful reproduction.

Some of the efforts of our movie makers to produce realistic effects are painfully amusing to one who has any knowledge of the technical considerations involved. There is a scene on the screen showing a canoe being paddled down a stream in an enormous canyon. The canoe is almost an insignificant speck, a dot in the void of a great spectacle of nature. Strange as it may seem, one hears the dip of the paddle. One who knows the making of the talkies can visualize a stage-hand standing beside a tank of water placed under the microphone and dipping a paddle so that the great American movie audience will be treated to a bit of realism. The whole scene was incongruous enough to make a school boy laugh.

Realism in talkies will not come as an over-night development. It is something that must be fathered, something that must be nursed, something that must grow out of a multitude of unpardonable mistakes. It is something that must be first felt and then learned. However, when one considers that we have had nearly three years of unrestrained talkie making, one is inclined to believe that the perfection of realism has not been as rapid as it should have been. Let us take another example of bad talkie making.

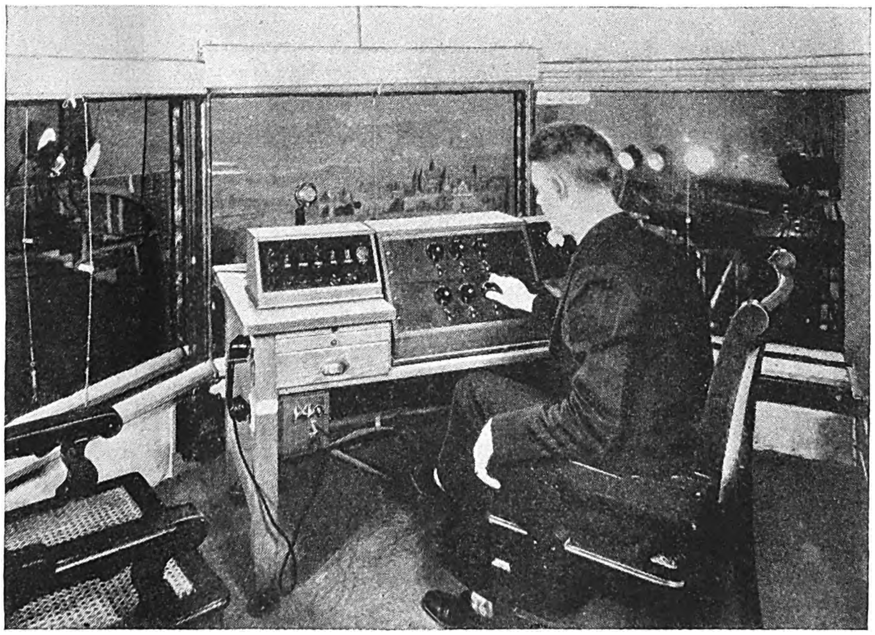
THE scene is a living-room. There is a normal conversation taking place between the occupants. The recording is, on the whole, fairly good. There is a quick flash to the platform of a railroad station. A locomotive with a string of Pullmans rushes into the scene and stops. The effect is terrible. What has happened? The sound produced by the approaching locomotive, a locomotive that one would think almost knocked the tripod from under the camera so closely did it approach, had a volume that was not much greater by comparison than the voices that immediately preceded it in the living-room set. The effect was strikingly incongruous. There was no dramatization at all. The locomotive should have thundered into the scene with a rattle of monstrous iron wheels, with the screaming of brakes and with the glamour and noise that always attends the approach of such gigantic pieces of mechanism. This particular locomotive really almost whispered its way into the scene.

It might be confessed here that the technical equipment in present use is not designed to handle the recording of an approaching locomotive the way the recording of an approaching "he" locomotive should be handled. There is some question as to whether or not this terrific high level of sound intensity could be passed through the amplifying tubes. The question arises: "Why would it not be possible to arrange an automatic switching in of additional amplifying equipment and additional horns so that the whole theater would resound with the thunder of the great iron horse?" It is true that sound amplification, when the sound takes the form of noise, can be amplified to a tremendous extent without the audience becoming at all aware of any distortion. When the sound of an orchestra is recorded the engineer must take care to keep the mould of distortion cut away but when he is recording noise such as the eruption of Mt. Vesuvius or a battle scene, the "sky is the limit." Perhaps we may look forward to the day when locomotives will be locomotives and battle scenes will sound more realistic than Boy Scout Troop No. 125 having their annual outing.

At the present time it is the general practice to place the ear of the "talkies," the microphone, in the center of the set. The technical reasons for this practice have never been made quite clear to the writer. Would it be unreasonable to assume that the microphone, representing as it does the ear of the audience, should be placed at the front of the set in a position bearing the same relation to the performers that the audience bears to the screen? With the microphone assuming this position it would appear that a portion of intelligent monitoring might, to a certain extent at least, be automatically solved.

A still more glowing example of bad manipulation of equipment was recently made obvious when a performer entering an extremely deep set from the back, walked into a close-up as he talked. The monitor had made no effort to fade him in. The sound effects were distinctly displeasing and somewhat incongruous when one realized that a sixty thousand dollar oriental rug adorned the floor and the room was furnished with a carload of expensive trappings fit for kings. There is no expense to which a well-managed studio will not go when it comes to supplying the necessary furniture and equipment and scenery for a major production. It makes one wonder why the smaller details of sound recording are permitted to pass by practically unnoticed.

IT would seem that sound recording is now in the same state of perfection that photography was in 15 years ago. This sorry state of affairs has been brought about by giving the technicians, the sound engineers if you will, too much of a free hand at the studios. Their judgment is in no case tempered with artistic sensitiveness; they cannot see the woods for the technical trees. They are interested in curves and technical precision and they have quite forgotten that technical precision is a far cry from artistic realism. It matters not to the man in the audience whether a tube is biased correctly or whether a resistance deviates one watt or 50 watts, he has come to the theatre to see life lived on the screen, to see an illusion that will be so perfect as to cause him to forget about his daily troubles, his trials and vicissitudes, and the sooner the talkies can deliver this message to him in the true, unvarnished voice of life, the sooner the talkies will be here to stay.



The monitor operator sees all and hears all. He should be part technician and part artist, for by a twist of the wrist he can improve or mar a sound record

A herring gull in full flight showing the slots of its wings opened

A sailing kingbird flying slowly. Primary feathers are outstretched but the false wings forming slots are barely visible

BIRDS HAVE NATURAL SLOTTED WINGS

By RAY P. HOLLAND, Jr.

SLOTTED wings seem to be one of the most recent of the greater aerodynamic developments. It has been in comparatively recent years only that they have been used to any extent at all. As they are used on the airplane, they seem to be one of the man-made devices which have no parallel in nature. There are many such things that appear to have been developed entirely in a scientific laboratory or as the result of continual development of complicated theories. When the result is finally reached and the product is finished, the general opinion is that something entirely new has been made. Then, suddenly, it becomes known that the identical thing that man has worked so hard to attain has existed all the time in a rather simple and surprisingly perfect application in nature.

Slotted wings are an excellent example of this. In nature they are almost as old as flight itself. The earliest flying creatures had no feathers. They flew with a skin web as the supporting surface, as does the bat. With the development of feathers, the primitive slotted wing appeared. That which corresponds to the fingers of our hand became the long, stiff feathers that form the wing-tip of the bird. The thumb developed, on the bat, into a projection to aid it in clinging to walls. On the bird, it became what has been known as the "false wing" or "bastard wing."

The false wing consists of a small group of long, stiff feathers above the leading edge slightly less than half the distance to the wing-tip on most birds. In its normal position, it fits into the conformation of the wing so well that it is not easily seen. When open, it is plainly visible. Being directly in front of the more flexible portion of the wing, it is in a perfect position to direct the airflow over the lateral control surfaces. Thus, in its function it is like the airplane slot.

The manner of operation is slightly different. Naturally, because of mechanical reasons, the bird can not open its slot directly to the front as on the airplane. The means it uses is to move the tips of the slot feathers forward and downward with the joint where the group connects with the wing proper as the pivot. The portion of the wing left exposed by this motion is very well shaped to produce high lift. The feathers of the false wing are disposed so that the cross-sectional shape of the airfoil they form is easily altered. When the slot closes again, the feathers shape perfectly into the wing. It is the ability to change shapes and areas at will that gives the bird such a remarkable control of its flight.

The primary feathers that form the wing-tip of a bird have an aerodynamic action somewhat similar to that performed by the bastard wing. The quill of these feathers is close to the front edge. Each feather is an airfoil in itself. They are arranged so that in overlapping, the leading edge of one feather is above the trailing edge of the feather in front of it. The nearer the end of the wing they extend, the more they diverge, until before the tip is reached, there is space between the individual feathers. The effect is that near the wing-tip there are several airfoils at high angles of attack, one behind the other, the whole group forming one large airfoil. Although not exactly like a multi-slot wing, this arrangement probably has some similar characteristics.

IT is likely that the tips of the primary feathers, which are free to twist over certain limits, place themselves in positions with negative angles of attack when the bird is in certain attitudes. This would form a true multi-slot wing. Mechanical difficulties prevent man from using such a wing, although he understands its action perfectly. This type of wing using numerous slots has been tested in a wind tunnel up to over 40 degrees angle of attack without reaching its "burble" point. The bird probably makes use of the principle in landing and in slow flying. At that time, the tip feathers are spread wide. In rapid climbing, maximum lift is obtained in the same manner.

When high-speed level flight or a dive is desired, the bird's wing-tip moves to the rear in relation to the rest of the wing; folding closes the openings between feathers. In addition to closing the slots, this action furnishes a desirable sweepback. Moving a supporting surface to the rear will move the center of pressure in the same direction and steepen the dive. In extremely rapid dives, birds fold their wings until they are scarcely stubs on the sides of the body. In this means of airfoil modification, natural flight has one of its greatest advantages over artificial flight.

The very shape of the wing-tip feathers is strong evidence that they act as individual airfoils. They are flat and of practically uniform chord out to the point where they are spread wide enough to cause a space between them when the wing is spread. At that point there is a sudden tapering of the plan form. The part of the feather in front of the quill narrows down almost to nothing. The feather becomes an efficient airfoil instead of only a component in an arrangement that makes up one large surface. The cross-sectional shape of these feathers is usually similar to that used on our racing planes, but even thinner. It is so thin, in fact, that it would not be practicable to construct an airplane wing using the same proportions.

As an example of a bird which uses its slotted wings to great advantage, let us consider the wild duck. Certain species of them migrate from as far north as Alaska in the summer and southward to the Gulf of Mexico in the winter. When not disturbed, they prefer not to fly, unless they have a certain destination. In their flight to that destination, they travel in a straight line at a high speed. When disturbed, they must be able to climb almost vertically for their protection. Also, they possess a marked ability to change direction and speed suddenly when they see something that arouses their suspicion.

Suppose that an order should be received in an aircraft factory for a ship of very high wing-loading, the nearest thing possible to a racing plane, that would have a low landing speed, an ability to stunt, extremely good climb, and also be capable of long-range non-stop flights. It would be absurd to try to fill all the specifications in a single ship. Any one of the requirements could be fulfilled in a specialized job for that purpose, but no individual plane could possess all the qualities necessary. Nevertheless, a duck can do all those things.

After flying all night at a high altitude, the duck reduces its wing area to almost nothing, shifts its center of pressure to the rear, and begins a long bullet-like dive to just above the surface of the water. At that point, it increases its wing area and resistance at the same time. As its speed diminishes, the false wing moves forward from its position to form the slot. It maintains perfect lateral control up to the point when it becomes practically motionless in the air only a few inches over the water. Then, with a few flaps of the wings, it lets itself down easily. If it is disturbed, it springs from the water with amazing alacrity. A rapid and steep climb is maintained until the bird is out of danger. During this climb, the slots are continually open. They are, more than any other one thing, responsible for this performance. They increase the lift and prevent "burbling" in the attitude necessary for the climb.

DIFFERENT birds, depending on the degree to which they use them, have slotted wings developed to different degrees. Generally, the false wing is comparatively small on gliding birds. They are slow fliers that employ extremely efficient airfoils. Birds such as the albatross derive their efficiency from a supporting surface of very high aspect ratio. Their light wing-loading provides a sufficiently slow landing speed for them. Great climbing speed is unnecessary because they fly over level stretches of water with only slight changes in elevation. Their continuous gliding is made possible by the rising currents of air caused by the swells of the sea. Birds utilize these slopes of water in exactly the same manner that a sailplane uses a long gradual hillside.

Those birds which have a high-speed flapping flight have the slots developed to the greatest extent. They are birds of very high wing-loading. High-speed wing action is necessary in order to maintain flight. Nevertheless, a remarkable rate of climb and a reasonably slow landing speed can be produced. Quail, grouse, and pheasants are birds of this type. Examination shows that these birds have abnormally large bastard wings.

I have noticed that the position of the slot varies on birds of different sizes. To illustrate this, I will compare the Hutchin's goose, which weighs about eight pounds, to a representative small bird. The center of the group of feathers, on the goose, that constitutes the bastard wing, is approximately 58 percent of the distance from the body to the tip of the wing. On the smaller bird, it is only 37 percent of the distance out. The smaller bird's false wing occupies slightly over 20 percent of the leading edge, while that on the goose occupies only 17 percent of its leading edge.

HOWEVER, this latter comparison creates the wrong impression because the goose is a bird of high aspect ratio while the other is not. The slotted wing area of the goose is much larger in comparison to the entire wing area than is the case on the other bird. Its wing-loading is considerably greater also. The manner of flight, in the same way that it affects the size, is likely to have a direct bearing on the position of the false wing.

On the ruffed grouse, a bird of heavy wing-loading that flies with an extremely rapid wing action, the slot feathers are very close to 50 percent of the distance to the tip. On birds of light wing-loading it is usually less than half way out. These observations indicate that the bastard wing, viewed from a standpoint of size and position only, has a direct relation to the size and flying characteristics of the bird, and must be a part of its control system, and not merely a useless appendage.

If you would like to see a practical example of the actual means the bird uses to open his slotted wings, it is only necessary to obtain a bird's wing to experiment with. This should be easy, for there are many species of detrimental birds, such as the hawk or crow, that may be killed at any season. The wing of the bird, cut from the body, is all that is needed. There is a tendon just in front of the wing bone. As this is pulled the wing starts to unfold. Everything goes on normally with the false wing in its original position until the maximum wing area is reached. In landing, the bird would employ this position of its wing in order to have the lightest wing-loading, and consequently the slowest landing speed. It is also in landing that it makes the greatest use of the slotted wing. It is, therefore, logical that the action of the false wing should be governed by the tendon that holds the wing outstretched.

By pulling with slightly more force on the same tendon, the false wing will move forward and downward into its correct position to act as a slotted wing. When actually seen operating in this manner the function of the so-called bastard wing is very evident.

ACTUAL photographs showing the slots open on flying birds form the only more convincing evidence I know of. It is difficult actually to watch birds and see the system in operation, even with binoculars. The opening is slight and there is only a short period of time during which to observe it. It may be seen after much effort but not distinctly enough to be a proof. However, to take a wing in your hand and actually make the slot open, will make even the most stubborn doubter stand convinced.

•

Instruction in "blind" flying is becoming increasingly important to the aerial transport industry. An article telling how it is carried out is scheduled for early release.

NOW YOU CAN BUY INSECTS FOR 10 DOLLARS A MILLION

TEN dollars a million for insects! Who'll buy? The average stung, bitten, and be-itched picnicker or camper may ask wearily why anybody should want to buy a million insects at that price when you get more than a million for nothing every time you show your nose out of doors.

But the insects that are worth 10 dollars a million are cheap at the price, for they prey on the eggs of other insects, thereby preventing the pests from ever seeing the light. They are the almost microscopic wasps known as *Trichogramma,* which are reared in captivity by Stanley E. Flanders, entomologist of the Citrus Experiment Station at Riverside, California. Mr. Flanders has been at this work for some time now, and has improved his rearing methods to a point where the tiny parasites can be produced at a thousand for a cent. They are shipped out in great numbers to orchardists, who release them to assist in their endless warfare on fruit-spoiling insect pests.—*Science Service.*

Recently developed safe, fireless lamp for flashlight photography

NEW PHOTO FLASH LAMP

A FIRELESS, smokeless, odorless, and noiseless photographic flash lamp has been developed by the incandescent lamp department of the General Electric Company, Cleveland. The flash is confined entirely within a bulb, with resulting advantages that are expected to revolutionize flashlight photography. Requiring only one-hundredth of a second to act, and being without hazard, it will make possible the taking of flashlight photographs in places heretofore practically impossible to "shoot," such as in trains, airships, and theaters, under water, and by insurance companies requiring night photographs under all weather conditions.

The lamp consists of a clear bulb of standard design, with the flashlight filament coated with a special preparation, and with a quantity of very thin aluminum foil in crumpled sheet form within the bulb. The bulb is oxygen-filled.

When the circuit is closed the filament is lighted and this, in turn, lights the foil. The lamp operates on any 115-volt house supply, or with dry, storage, or flashlight batteries. A new lamp is needed for each flash. The lamp is most efficient when used with suitable reflector equipment.

NEW PROCESS FOR CARBON BLACK MANUFACTURE YIELDS HYDROGEN

THE production of carbon black from natural gas has been, heretofore, a wasteful process, but experiments carried out by the United States Bureau of Mines give promise of an increased yield of more than 400 percent.

The old method, and the one in widest use, consisted of burning natural gases incompletely and collecting the unburned carbon on cold metal surfaces when the gases passed off. Sometimes the carbon black was collected by filtering the gases through cloth.

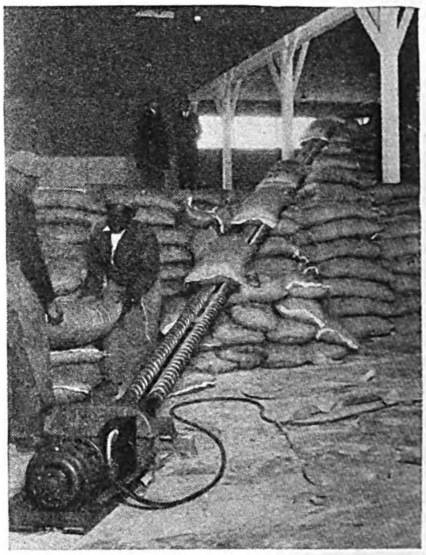
The new method calls for the passing of the gases through ignited coke. The coke is fanned to great heat by subjecting it to a forced air draft, after which the natural gas is passed through it and cracked.

An advantage to be gained by the new process is that, in addition to the carbon black, hydrogen may be recovered and used in some localities for the synthesis of motor fuel and the manufacture of ammonia and other products.—*A. E. B.*

DOUBLE-SPIRAL CONVEYOR

A NEW portable, flexible, power-driven, elevating and tiering conveyor has just been introduced and has already found many useful applications in a wide range of industries.

The TwinVeyor, as this new apparatus is called, uses a new principle: two external spiral tubes are turned toward each other by a power head. Anything placed on the conveyor travels forward rapidly, perfectly balanced. It is used for handling raw materials and finished products in bags, bales, and bundles. The equipment finds other applications handling crates and boxes, and experiments are being made handling the finished product itself, without packaging, where its shape and size permit the spirals to get hold of it. It carries bagged sugar up a 30 percent grade at the rate of 90 feet per minute, handling 1800 bags per hour.



Double spiral conveyor for bags and bales. It is motor operated

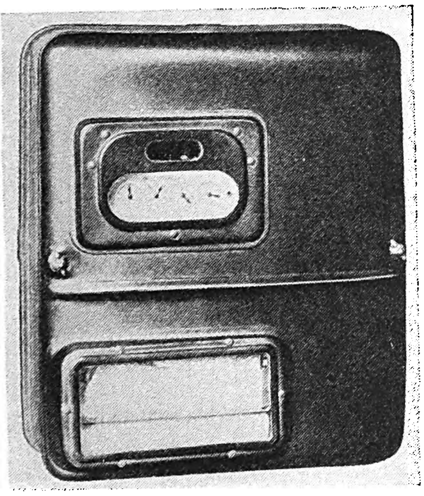
A standard unit consists of six eight-foot dual sections and a power head which draws current from any power line. Each section joins to the assembly with an automatic lock. It is easily shifted about by one man and the entire 50-foot line can be assembled or disassembled in six minutes. Flexibility is secured by the ability of any joint to take a 15 degree angle horizontally, 15 degrees up or 10 degrees down.

A hurdle section permits any number of TwinVeyor 50-foot units to be hooked together, forming a continuous line of any desired length. The traveling load hurdles each power head in the line. Right and left spiral chutes are provided for shunting the load from one TwinVeyor line to another without manual handling, thus making right-angle turns simple.

MEASURING ULTRA-VIOLET RAYS

THE element of danger in the indiscriminate use of the ultra-violet ray has had to do with the dosage, the amount of exposure, the proper measuring of ultra-violet radiation for the purpose at hand. It has heretofore been a difficult task to measure this amount exactly, but now there is an ingenious device for the purpose, an ultra-violet ray meter that records the amount of ultra-violet rays coming one's way as accurately as an electric house meter gives the amount of electricity one is consuming in the home.

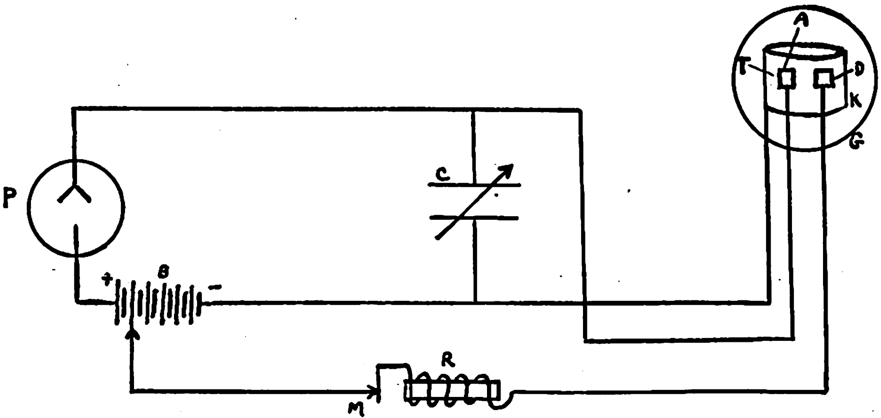
This indicator operates from dry cells within it. Its essential element, the "eye" of the instrument, is a photo-electric cell which was developed by Dr. H. C. Rentschler of the Westinghouse Lamp Company. The cell in this case is sensitive only to those light rays supposed to have therapeutic value or other effect on vitality—rays .0029 to .0031 millimeters in wavelength. The cell itself is the result of research findings that: (1) By a proper selection of the active material, a cell may be obtained that will not respond to light of longer wavelength than that desired; and: (2) By use of proper light filters it will not respond to light of shorter wavelength than that suitable for the purpose. (A cell of uranium metal and Corex D glass, for example, responds only to that band of light used in prevention and cure of rickets.)



Graphic meter for recording the quantity of ultra-violet on a chart

When the rays strike the cell of the meter, a certain amount of current passes through it, proportional to the intensity of the rays, and charges a condenser which, when fully charged, trips a counter. The operation is then repeated, each impulse measuring a definite quantity, irrespective of the light intensity. Since the unit of measurement has at present no name, the value taken is arbitrary. Over a given period of time the number of impulses per minute, each accompanied by a "click," thus indicates intensity, while the total number of impulses indicates quantity.

The principle on which the meter operates is as follows, referring to the diagram: A battery B charges condenser C at a rate determined by photo-electric cell P when light falls upon the cathode. Glow tube G has metal cylinder K for cathode and a primary anode A and main anode D. A small gap exists between A and cathode at T. When C is charged to a potential such that a discharge takes place between A and K, the cathode resistance of the glow tube is broken down and current flows between D and K. This operates the relay R, registers the count, and opens the main circuit M. The condenser is discharged simultaneously. The operation is then repeated. The total quantity of light falling on P is proportional to the total number of discharges registered.



The circuit of the instruments used in the ultra-violet ray meter

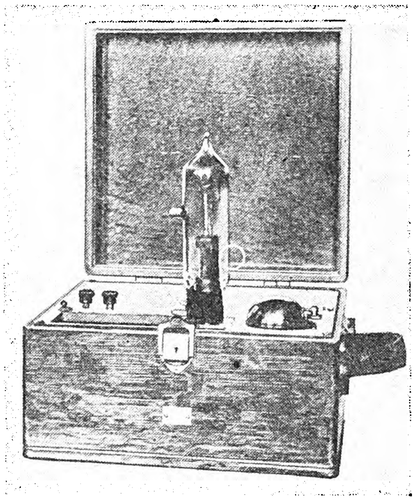
WOOD ALCOHOL

WITHIN recent years it has become possible to produce synthetically the wood alcohol that was formerly prepared only by destructive distillation of wood. The substance is now manufactured from water-gas and hydrogen at a cost which makes it possible to produce large quantities at a low price. Modern industry is, therefore, attempting to introduce the substance for a large variety of purposes, including its use as an anti-freeze mixture in automobile radiators. It is also used in the manufacture of quick-drying shellacs and varnishes. It has long been known that wood alcohol is a dangerous poison with cumulative effects. When taken frequently in small doses, it produces blindness; in large doses, it causes death. The added danger from this product is in the fact that the repeated inhalation as well as the drinking of very small doses of the poison may produce the most serious results.

If this substance is to be used as an anti-freeze mixture in the coming winter, employees of garages who will inhale large amounts of it from overheated radiators are likely to suffer serious injury as a result.

Cases have already been reported in which women and children who have used quick-drying shellacs or varnishes, made with methanol, in closed rooms have suffered harm as a result. In the great spray process used in automobile factories, the spraying is done under hoods and employees wear masks, so that they are protected against the hazard.

As is usual in modern industry, the name of the product has been concealed by the bestowing of fanciful names and the average person does not recognize under the name *methanol* or some other fanciful title the old, old hazardous wood alcohol.—*M. F.*



Ultra-violet indicating meter which uses a special photo-electric cell

FEATS OF SHORT WAVES

RADIO waves which will do the family cooking, provide wireless illumination for homes, alleviate pain, and cure disease are the goal of new investigations into the possibilities of the short-wave high-power vacuum tube, according to Dr. Willis R. Whitney, director of the General Electric Research Laboratories, in a research narrative issued by the Engineering Foundation.

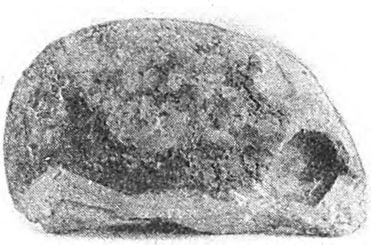
Control of this power for practical uses will immediately open up lines of advance in industry and therapeutics hitherto closed to science, it is stated. Simplified mechanisms and a reduction in the cost of producing large volumes of radio energy are the problems now facing solution.

Radio cooking has already been demonstrated in tests with the new tube.

"A wire was suspended over a table,"

Dr. Whitney states, "at a distance of a few feet from the radiating aerial, which was a copper bar about 10 feet long. A sausage in a glass container suspended from the end of the wire was soon cooked. Likewise an egg was 'fried' in this container, and an apple spitted on the end of the wire was thoroughly baked in a short time. .

"With suitable changes of utensils, cookies were baked and water boiled. There were no flames or other visible evidences of heat accompanying the cooking. The vacuum tube from which this weird power emanated was only two feet long and five inches in diameter.



Robert P. Robinson of the Skelly Oil Company, found this stone at San Angelo, Texas. Its resemblance to a human skull is striking, but since it came from rocks of the early cretaceous period, thus making it something like 115,000,000 years old, scientists are not inclined to take its human origin at all seriously

"As yet the high-power short-wave vacuum tubes are being used for experimental purposes only. To bring them into practical usefulness at reasonable cost and discover their many possibilities for service to mankind is now our task."

BLOOD PRESSURE

THE blood pressure of human beings is measured by putting an elastic cuff around the arm, inflating it with air, and then listening to determine the points at which the sound of the blood in the vessels is extinguished and the point at which it again appears when the pressure of the cuff is released. This simple test has been of tremendous importance, particularly in examinations for life insurance. A normal blood pressure is recognized as being approximately 120 millimeters of mercury. Insurance companies insure persons with pressures ranging from 100 to 140.

In order to make some more exact determinations regarding blood pressure of a considerable group under controlled conditions, Drs. W. C. Alvarez and L. L. Stanley took the blood pressure of all of the prisoners in the San Quentin prison in California. They are inclined to believe that there is a normal blood pressure for each person; that if a person has a high blood pressure at 20 years of age, he is likely to have a high pressure at 40. The lower limit of normal pressure they found to be 90 millimeters of mercury and the upper limit 140. They found the normal pressure about 115, which is lower than the figure usually found for men out in the world. The reason for this they consider to be the fact that the prisoners are not fatigued and worried by the struggle to make a living. They did not find that alcohol affected the blood pressure, but tobacco appears to raise it about 4 millimeters.

Men who have been convicted of murder in the first degree showed a blood pressure slightly higher than that of other prisoners of the same age. They found that the prison guards had a pressure considerably higher than those of prisoners, which they consider to be due particularly to overweight, and also to the fact that the guards were applying for positions at the time when the pressures were taken and that many of them were anxious for fear they might be rejected.—*M. F.*

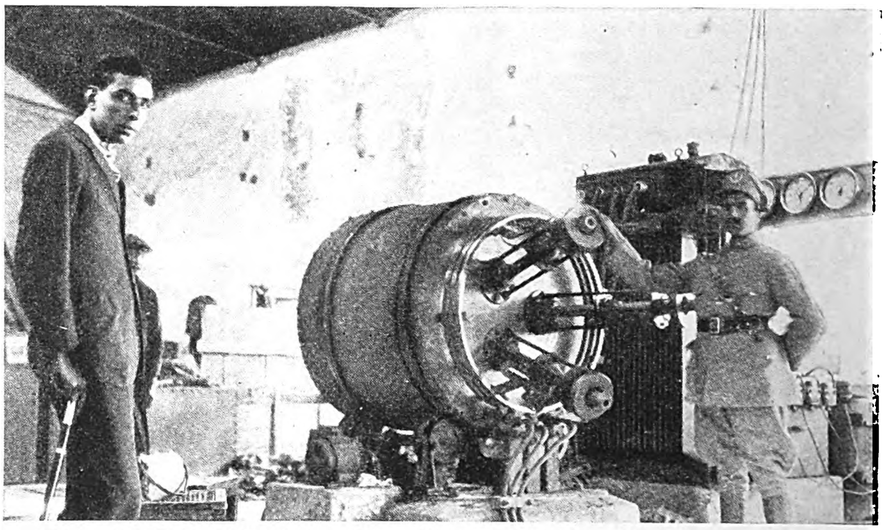
POTATO RUBBER

THE Firestone Tire and Rubber Company is experimenting on the commercial value of a new variety of rubber with potato starch as the base. The synthetic product contains no latex or plantation rubber. It is made by mixing the starch with chemicals which coagulate it into a gum-like substance differing from rubber only in that it is less elastic.—*Barron's.*

REFRIGERANTS FROM THE TROPICS

"YOUNG as we are," says Dr. H. E. Howe, editor of *Industrial and Engineering Chemistry*, "we can remember the days when sailing vessels carried cargoes of natural ice from Maine to Cuba, and we believe even as far as Calcutta. How times have changed!

"There is now en route to New York from Mexico one of three vessels, each of which has been equipped with a compartment insulated against heat exchange by 12 inches of cork board to bring solid carbon dioxide to the metropolis for refrigerating purposes. One of the petroleum companies in drilling for oil struck a supply of carbon dioxide which rushed to the surface at a pressure of 1000 pounds.



Even turbulent Afghanistan, where kings are made and unmade overnight, must have coins. Here is shown the electrical smelting machine, imported from America, which has just been installed in the mint at Kabul, the capital. Beside it stand an army officer and a modern young Afghan "intellectual"

"It is much too early to discuss the economics of this venture. Inasmuch as the solidified gas must be cleaned of its impurities before it can be re-made into commercially pure solid carbon dioxide, it is doubtful whether the natural high pressure will be of much advantage, and undoubtedly there have been some nice technical difficulties in the purification of this particular supply of gas. We have yet to learn, too, with what efficiency and what percentage of loss the solid gas has been stowed in the hold, transported, unloaded, and distributed. These are technical details concerning which no information has so far been made available. However, the whole venture is intriguing. The mere thought of preparing a refrigerant in the tropics for shipment into the temperate zone is so complete a reversal of the old established practice as to afford another example of how chemistry is helping to remake the world."—*A. E. B.*

NEW INSECTICIDE PRODUCED BY "CUBE ROOTS"

IT used to be a favorite wheeze at college to suggest to the room-mate who had prematurely squandered his allowance that he write home for funds with which to buy a cosine for use in mathematics class. We used to assume that Dad either had never been exposed to trigonometry or had forgotten that a cosine was merely a mathematical function of an angle and that he would "enclose check" rather than admit ignorance. We were forcibly reminded of that ancient practice by a recent statement in a publication of the staid United States Bureau of Agriculture, when we noticed the sentence "cube roots are not yet available commercially."

We still think Dr. R. C. Roark, of that department, had his tongue in his cheek as he wrote that sentence, but further investigation revealed the fact that "cube" is a South American plant and like most other plants, it has roots. (The plant's name, incidentally, is pronounced koo-bay.) In the course of this reading, we learned further that the cube plant has been found to contain a substance called rotenone which has been found to be an excellent insecticide. The Department is therefore urging the Malay States to grow rotenone-bearing plants on a commercial scale for

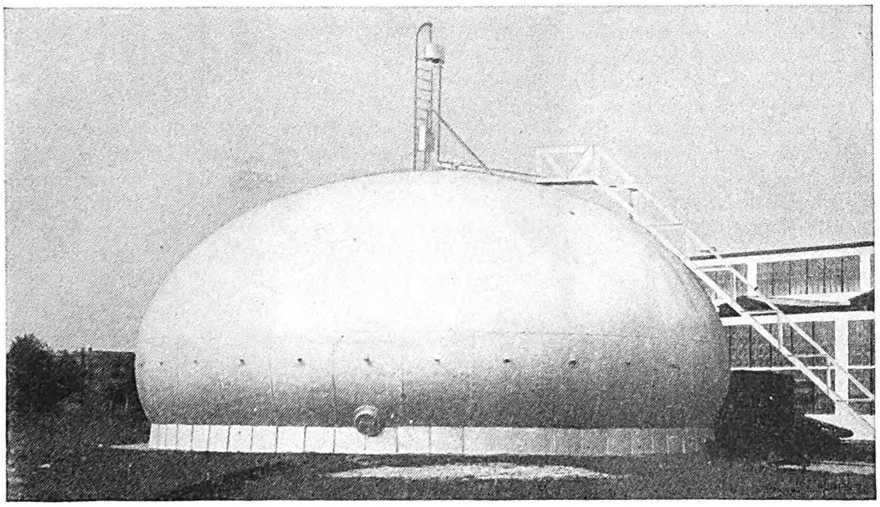
American trade. This new insecticide is found in quantities up to 7 percent in the root of the South American cube plant, up to 5.5 percent in derris roots, and to a lesser extent in three other plants. The cube plant now grows in a part of South America where the climate is similar to that of the Malay States and surrounding countries.

Tests by the Department of Agriculture indicate that rotenone is highly poisonous to both sucking and chewing insects. In tests conducted privately, rotenone was fed to dogs, cats, sheep, and chickens in quantities up to 1 grain per pound of body weight and no injury was noticeable.—*A. E. B.*

KETOGENIC DIET IN EPILEPSY

IN 1921 it was suggested that children with epilepsy might have the number of their attacks greatly reduced by providing them with a diet low in protein and containing large amounts of fat as compared with the amount of sugar taken into the body. This is called a ketogenic diet, because it tends to produce an excessive amount of ketones and their derivatives in the blood and in the excretions. The diet must be carefully watched, since an excessive amount of this substance produces serious symptoms.

Recently, Drs. Henry F. Helmholz and H. M. Keith have recorded the results of this diet on 272 children who had suffered with epileptic attacks. Two hundred forty-three children with epilepsy of unknown origin, in that the attacks could not be related to any disease or surgical disturbance, were treated by this diet. One hundred seventy-one of these children cooperated fully. One hundred forty-one children had been on the diet more than a year and 30 had been treated less than a year. Of the 141 patients treated for more than one year, 43 patients had remained free from epileptic attacks from one to seven years, and 32 others had shown definite improvement, as evidenced by the decided improvement in the number and severity of the attacks and by improvement in their general demeanor.

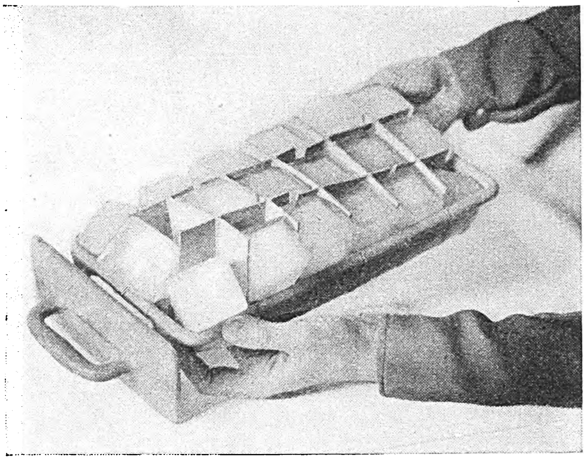


Looking like a huge drop of water on some oily surface, this Hortonspheroid holding 10,000 barrels of oil, was built for experimental purposes at Chicago

It has been argued by some observers that dehydration of the body is an important factor in the lessening of the convulsions. The investigators admit that this plays a part, but do not believe that it is the only factor.

Apparently 30 percent of the patients with epilepsy of unknown origin are freed from convulsive seizures by the use of this diet and, under completely controlled conditions, as many as 37 percent may be relieved of their disturbance. It is, of course, impossible to keep such children in hospitals over many years, and it becomes necessary for parents in the home to learn how to handle the diet and to take care of the child properly.—*M. F.*

Ordinary ice cube trays of automatic refrigerators are unsatisfactory because it is difficult to remove one or two cubes without emptying the tray entirely. A flip of the finger, however, is all that is necessary to remove just the number wanted from this new tray developed by the Frigidaire Corporation. It is made of strong rubber on a rigid steel rod frame



CHEMICAL PARADOX LEADS TO BETTER INSULATED WIRE

RUBBER is a non-conductor of electricity. Carbon black is a conductor. Therefore, it would appear natural that the admixture of carbon black in rubber would increase the latter's conductivity. In fact, this has been generally assumed to be the case until W. B. Wiegand and C. R. Boggs, in a recent issue of *Industrial and Engineering Chemistry* disclosed experimental evidence to the contrary. As a matter of fact, up to about 10 percent, by weight, of properly made and dried carbon black may be added to each 100 parts of rubber hydrocarbon present in rubber insulating compounds with marked improvement in dielectric strength, resistivity, and power factor, and without serious increase in dielectric constant of the rubber insulation.

The exact amount of carbon black required depends somewhat on which electrical property is to be brought to its maximum value.

This discovery is of importance to the makers of insulated wire who use a rubber covering next to the metal. In fact, these results would seem to render advisable the rewriting of many specifications dealing with rubber insulating compounds, and thus make it possible to apply the well-known beneficial effects of carbon black compounding—improved toughness, density, wearing resistance, imperviousness to light, tear resistance, and so forth—to the electrical insulation field, from which it has hitherto been barred.—*A. E. B.*

NEW OIL TANK HAS UNIQUE SHAPE

IF you were to visit certain oil company properties in Texas you would see unusual steel structures which have the appearance of giant mushrooms breaking through the ground. They are a new type of storage tank designed by the Chicago Bridge and Iron Works.

The Hortonspheroid, as this unusual shaped tank is called, is used to store high-test gasoline and other volatile oils. Such liquids are placed in the tank and the tank closed tight to prevent evaporation loss taking place.

It is possible to close the Hortonspheroid tight because it is designed to withstand a certain pressure, usually 10 or 15 pounds per square inch. As the temperature rises, the pressure increases but no vapor escapes. Each installation is, of course, equipped with a safety valve.

But why the unusual shape? It is simply the shape which a flexible container would take if filled with liquid and subjected to a few pounds pressure. It is the most natural shape for such conditions and, by the way, the most economical one, as all of the metal used in its construction is used effectively.

SWORD SWALLOWERS

THE sword swallower is able to pass a long knife down his throat by developing a special agility in the movement and by developing also the ability to breathe by movements of the ribs without moving the diaphragm. That fact was recently determined by three French physicians who subjected two sword swallowers to a

Seated within the cabin of a large airplane, the young lady above wears the parachute harness which is covered with a velour jacket. At right, she has snapped the simple parachute hook into the harness ring

physical examination, using both the X ray and the esophagoscope, an illuminating device which enables the physician to look into the tube through which food passes when swallowed.

The use of this device, the esophagoscope, revealed the fact that there were no special abnormalities of the esophagus nor was its lining full of scars as might have been the case if the swords had cut it. The evidence indicated that the sword is passed down by making a straight line through the mouth, throat, and esophagus, and that cutting is avoided by holding the diaphragm still in the manner that has been mentioned. In order to be a sword swallower one has to be especially built as well as trained for the purpose.—*M. F.*

A QUICKLY ATTACHABLE PARACHUTE

WITH more and more travelers using aerial transportation, the question of parachutes for passengers in cabin airplanes becomes increasingly important. The Russell Parachute Company has developed a quick attachable parachute which promises to be most useful.

The passenger wears a harness covered by an attractive velour jacket. The velour-faced parachute pack is placed conveniently in a metal rack. The pack can be instantly removed from its rack, grasped by the hand holds on either side and with one quick movement engaged to the single steel hook in the harness breast plate.

The pack is in no wise different from the ordinary Russell 'chute and acts just as efficiently and dependably.—*A. K.*

A ROTOR AIRCRAFT

RECENTLY *The New York Times* published an interesting story on a "rotor aircraft," a photograph of which we reproduce here.

Piecing together the newspaper story and what we can deduce from the photograph of the craft (built mysteriously on a barge moored in Long Island Sound off Mamaroneck, New York) we analyze it as follows:

In the center there is a short fuselage or nacelle in which there are: a tandem cockpit; a Wright Gipsy, 90 horsepower, air-cooled engine used to drive the rotors; and at the front end, another engine driving a conventional tractor propeller with three blades.

The nacelle is mounted on a conventional twin float alighting gear (built by the Edo Aircraft Corporation).

The tail surfaces are not mounted at the end of the nacelle, but are carried by booms and outriggers.

The front engine and propeller constitute the propulsive system, differing in no wise from the ordinary propulsive system.

The Wright Gipsy engine, by some species of gearing keeps two large rotors in movement, one on each side of the fuselage. These rotors have a combined span of slightly less magnitude than would be the normal span for a seaplane of this size. The rotors are two feet in diameter and carry sheltering circular disks four feet in diameter at their ends.

At the time of the Flettner visit to America in his rotor driven ship, *Buckau*, there was much speculation as to the possibility of employing a rotor as the sustaining element of an aircraft. Theoretically, there is nothing impossible in this. When a cylinder is rotated in an airstream it experiences a side force of considerable magnitude. The principle of this side force was discovered by a German scientist by the name of Magnus more than 60 years ago. The Magnus principle explains the swerve of a baseball.

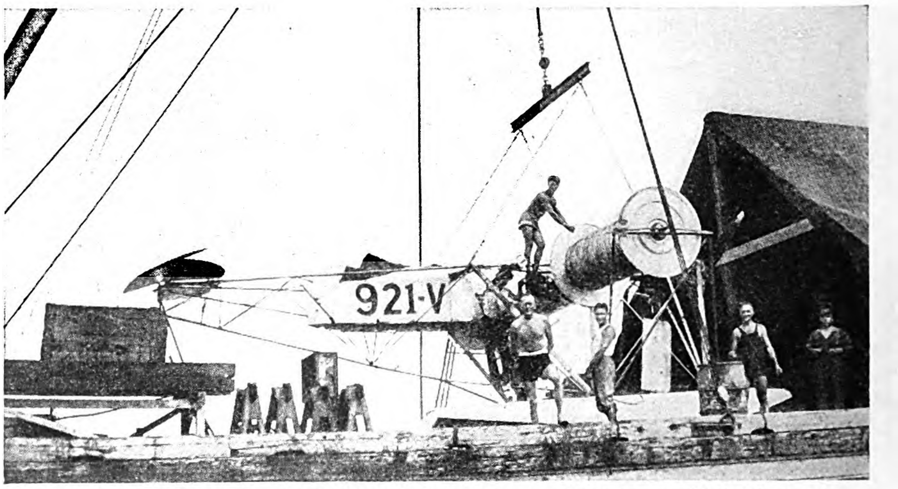
If the rotor aircraft is set in forward motion by the pull of the tractor propeller, and the cylinders are rotated so that the upper side is moving into the wind, the force acting on the lower side becomes a vertical or lift force.

For the same projected area of rotor, it is possible to obtain several times the lift of an ordinary wing—perhaps seven or eight times as much. Therefore the projected area of the rotor can be considerably smaller than the area of the equivalent airfoil and it is conceivable that for the same gross weight a more compact sustaining system can be used.

There are, however, two great difficulties to overcome. The ordinary airfoil, when the engine fails, acts very well in a glide. If the Gypsy engine should fail, the rotors ceasing to rotate would be deprived of lift and the craft might fall very rapidly. The other difficulty is one of efficiency. From experiments made by the writer of this note, it would appear that even when a long slim rotor is employed, and large sheltering disks are placed at the ends, the lift-over-drag ratio—the ratio of sustaining force to resistance of the rotor—is only five or six. For a good airplane wing, this ratio of lift to drag may be as high as 20. Therefore high speed and efficiency become difficult of attainment with a rotor as the sustaining element. It is clear that no rotating lifting element can be as efficient as a beautifully cambered wing. Perhaps the mysterious designers are perfectly aware of these facts and have already met the difficulties by advanced research. We shall await further news with real interest.—*A. K.*

GROOMING THE *DO-X*

THE Dornier *DO-X* is being actively prepared for its forthcoming flight across the Atlantic to the United States. Since its initial flight, the giant flying boat has undergone a number of important changes. In its early form, the power plant consisted of 12 air-cooled Jupiter engines



Wingless airplane, an adaptation of the Magnus principle on which Flettner's rotor ship operated, on the barge on which it was built in Long Island Sound of 475 to 500 horsepower each. The air-cooled engines were disposed in tandem in six nacelles. Some unofficial reports had it that the rear engines did not cool sufficiently well, particularly when taking off from the water. Other reports gave the giant boat a somewhat low performance. The change to 12 Curtiss Conqueror water-cooled engines of 600 horsepower would tend to substantiate the truth of both views.

With the water-cooled engines shown in the accompanying photograph of the *DO-X*, the radiator is in front in the slipstream of the front propeller, and both engines have an equal chance of cooling.

Those who remember the photographs of the *DO-X* published previously in this magazine, will note two other important changes. A small auxiliary wing, placed some four feet above the main wing, formerly connected all the engine nacelles. This wing has disappeared, and there is now but a simple streamline brace running from nacelle to nacelle in its place. Our opinion is that the interference between main wing and auxiliary wing was found to be detrimental to efficiency.

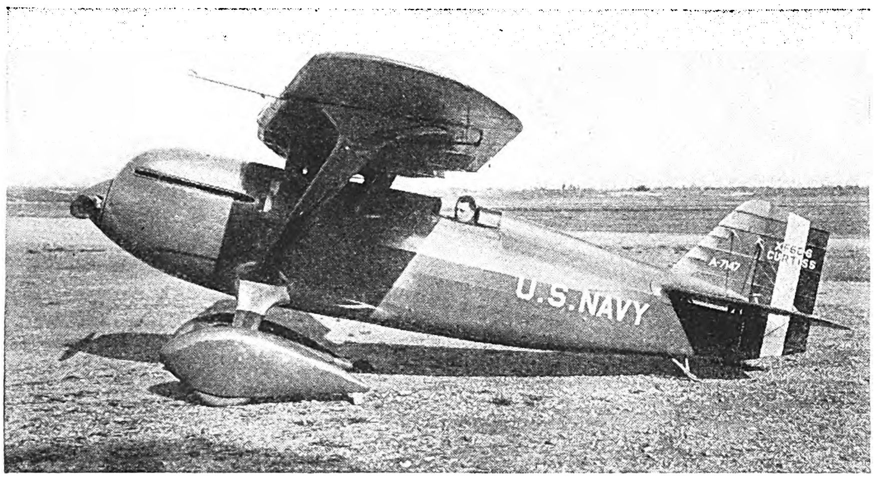
Another change is in the support of the nacelles above the main wing. This used to be in the form of a single gigantic streamline strut. Now this support is in the form of struts and braces of more conventional dimensions. Here, again, the large streamline strut probably diminished the lift and efficiency of the main wing. The large streamline support *per se* may have had less resistance than the present exposed nacelle bracing, but the interference between large strut and wing was another matter. The interior of the cabin has been re-decorated and re-furnished for the comfort of passengers on long flights. The interior now looks as comfortable as the salon of an ocean liner.—*A. K.*

THE SECRET OF AVIATION SPEED

CAPTAIN Frank Hawks, who recently crossed the continent in half a day, is an exponent of aviation speed. To an interviewer of *The New York Times*, he said, "I believe this last trip did prove that an aerial pony express on a 13- to 15-hour schedule between New York and the west coast is practical to-day. Why waste time loafing along at 100 miles an hour when planes can be built to fly 200 to 300 miles right now? Five hours to Miami, 15 hours to the Canal Zone, three to four hours to Chicago. That is the speed for our bankers who must send interest-bearing securities, and that is the speed our designers and engine builders must prepare for and prepare for soon."

The National Air Races at Chicago certainly backed-up Captain Hawks' point of view. This year saw the application of still more power, and also increased refinement in streamlining.

The picture of the re-vamped Curtiss Hawk pursuit plane serves to explain high plane speed. Here is a comparatively small plane, powered with a 600 horsepower Curtiss Conqueror engine. This engine, with tremendous heart, is small of body. It is completely enclosed in the beautifully streamlined body. It is water-cooled, yet we do not see a radiator! That is because the radiator is part and parcel of the wing. The cooling surface is also the covering surface of the wing, with water circulating in a multitude of concealed tubes. Cooling is thus obtained without any expenditure in head resistance. The wheels are streamlined in so-called "pants." There is but one wing, and the strut ends are carefully faired into this wing. The landing gear consists of but two cantilever struts, one on each side. There can be little further refinement in the attempt to gain speed.

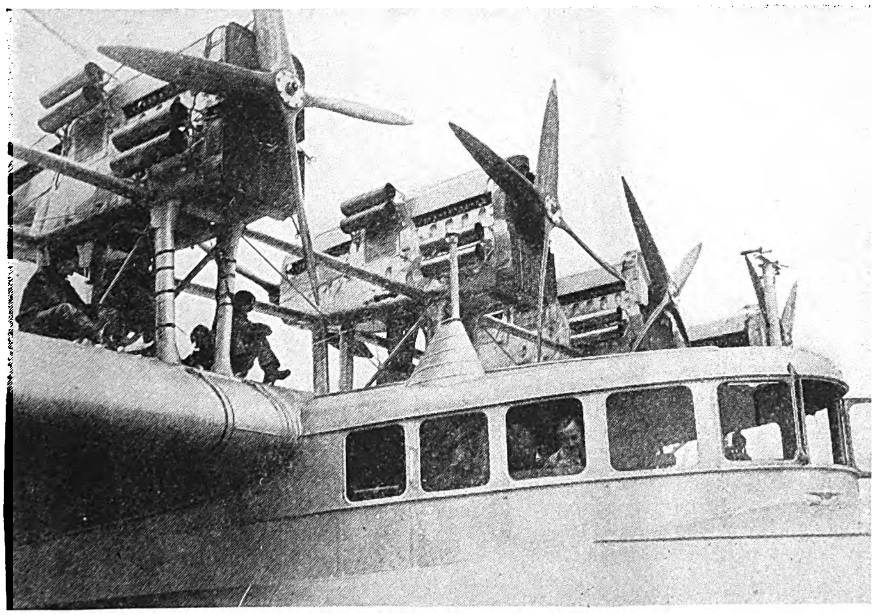


Trophy-winning Curtiss Hawk pursuit plane rebuilt for better performance. Most of the features described in the accompanying text are visible in this view

Such aerodynamic efficiency is part of the secret of airplane speed; lightness of structure is another part; and lightness of motor for high power is yet another. But there is one fundamental difference in principle which differentiates the airplane from all other methods of transportation as regards speed.

In all vehicles, be they surface vessels, trains, airships, or automobiles, the air resistance goes up as the square of the speed; the horsepower as the cube of the speed. That is why an ocean liner cannot be pushed beyond 30 knots or so, without the use of absolutely prohibitive power.

But in the airplane, the resistance is independent of the speed. It is dependent only on the aerodynamic fineness of the plane. If the fineness is high—if the ratio of lift to drag is 15—then one pound of weight will require only one pound of pull, no matter what the speed. Therefore speed can go up indefinitely. Some authorities claim 500 miles per hour to be the limit, because after that, air friction will set the plane on fire! But 300 miles an hour as a commercial speed is certainly within the limits of possibility.—*A. K.*

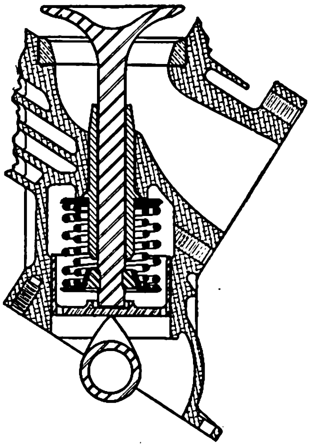


The Dornier *DO-X* in slightly revised form, with water-cooled Curtiss Conqueror engines, now being prepared for its forthcoming flight across the Atlantic

AVIATION FINANCES

AFTER the mad, though happy days of 1929, American aviation is suffering from the same depression that other industries are meeting. The President of Air Investors, Harvey Williams, paints a gloomy picture in his report summarizing 1929 and first-quarter-1930 conditions. The most important holding companies are probably United Aircraft and Transport, Curtiss-Wright, and Aviation Corporation. Aviation Corporation reported a first quarter loss of 863,651 dollars as compared with a loss of 1,441,000 dollars for the last six months of 1929. Curtiss-Wright suffered a loss of 1,620,920 dollars as compared with a loss of 668,000 dollars for the full year of 1929. United Aircraft and Transport reported earnings of 39 cents a share as compared with 89 cents for the first quarter of 1929. Inventories are still heavy, smaller manufacturing companies are disappearing, and production is very low. But there is a brighter side to the picture!

Colonel Clarence M. Young, Assistant Secretary of Commerce for Aeronautics, gives a totally different viewpoint in his report to Mr. Hoover.



Unconventional valve mechanism of the new inverted airplane engine

About 18 months ago, 35 companies were operating 59 different scheduled airlines over the airways and were flying a total of 69,000 miles every 24 hours.

At the present time there are 45 such companies engaged in the transportation of mail, passengers, and express, flying approximately 120,000 miles per day. These 45 carriers now operate 137 different routes.

Colonel Young foresees great progress when the provisions of the Watres Airmail bill are given full effect.

The first result under this bill will be the extension of the airmail to various parts of the country not now being served, because it will permit the Postmaster General to utilize the facilities of existing passenger lines.

Second; it will assist materially in the establishment of a more comprehensive passenger service throughout the nation by permitting present airmail carriers to go into the passenger transportation business.

While private flying is still lagging behind, this enormous and rapid growth in transportation will eventually give the manufacturers ample scope. More lines will mean more pilots, hence more students, hence more training planes.

No matter how gloomy the financial statistics of earnings, losses, inventories, assets, and so on, may look, the future of aviation is just as sound as ever. The slump is certain to be followed by a rapidly increasing prosperity of the whole industry. —*A. K.*

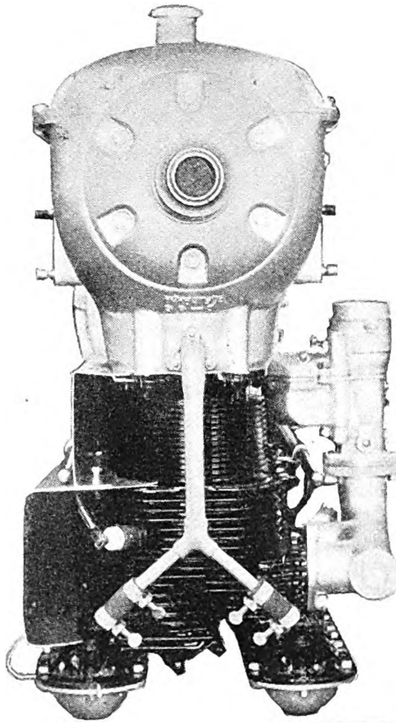
LOUIS CHEVROLET'S AIRCRAFT ENGINE

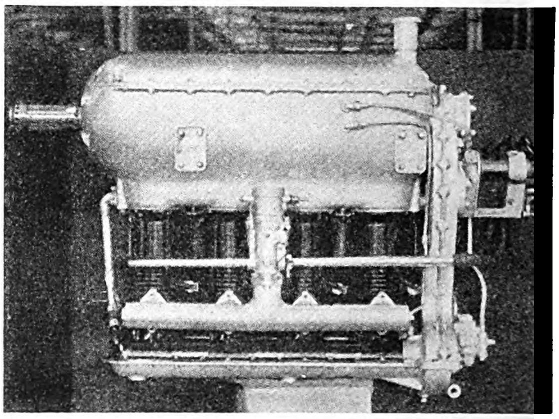
WELL known as the winner of many automobile races and the designer of racing automobiles, Louis Chevrolet has now designed an excellent aircraft engine, the Chevrolet "333." The fashion in low-power motors for aircraft now seems to run to the inverted, cylinders-in-line type, and it is to this category that the 333 belongs. The inverted engine, with the propeller-thrust line at the usual position, gives the pilot the best possible vision forward; the top of the crankcase is well below his eye, and there are no cylinders, exhaust stacks, or other impediments to sight.

The specifications of the 333 are interesting because they indicate that the popular four-in-line air-cooled type of engine is increasing in power and decreasing in weight.

Bore of the 333 is 4.5 inches; stroke is 5.25 inches; and piston displacement is 333 cubic inches (hence the name of the engine). It is rated at 120 horsepower at 2100 revolutions per minute and the weight (dry) is 260 pounds. Fuel and oil consumption is less than half-a-pound per horsepower-hour. (Aircraft engineers never think in gallons of fuel but in pounds, because weight is the important item rather than cost as is the case with the motor car owner.)

The air to cool such an engine must be carefully directed; the front view shows the scoop at the left side of the engine. Because of the special type of head, the cooling air passing through the scoop has no interference from the exhaust stacks—which are below—and strikes directly on the hottest part of the engine.





***Above:* Front view of the Chevrolet 333 engine showing, as a black square at the left, the scoop which directs the cooling air to the hottest part of the engine. *At right:* Side view of the engine. Looking over the smooth crankcase of this inverted engine, the pilot's vision is not obstructed**

The valve mechanism of the engine is unconventional and deserves special mention because the valves are actuated directly through lifter cups of Nitralloy steel. The cams strike the lifter cups a trifle off center, causing each cup to rotate every time it is struck. The valve springs are both wound in the same direction and each time the valve operates these springs have a tendency to twist the valve, thereby equalizing the seat. The entire valve mechanism is in a constant bath of oil and it is claimed that no adjustments are necessary. This should certainly be a great relief to the aircraft mechanic!

The special exhaust outlet enables the stacks to be placed under the engine, so that cooling air is not impeded and the exhaust pipe can be most conveniently located right under the engine. Carburetion is supplied by a Zenith down-draft carbureter. The down-draft principle is being rapidly accepted in aircraft practice.—*A. K.*

DO AIRLINES PAY THEIR WAY?

AIRPLANES do not pay their way, according to M. Henri Bouché, Editor of *L'Aéronautique* who presented a formidable statistical monograph to the first International Aviation Conference of the League of Nations.

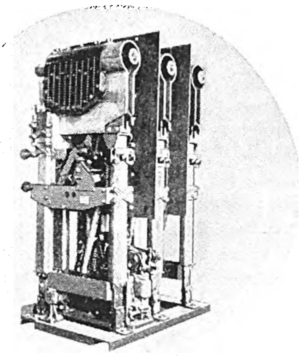
Each mile flown by commercial transport planes in 1929 cost British taxpayers about six dollars for lines going to distant parts of the Empire, and $1.28 for British-European lines. The French taxpayer suffered to the extent of $1.09 a mile, and the German 70 cents. In the United States we are proud of the fact that there are no subsidies to our airlines. But M. Bouché is of the opinion that, taking into account the high rates charged for airmail—considering weight, much higher than those paid by passengers—there is an indirect subsidy of about 70 cents per mile flown.

"The great size of the United States, its huge volume of urgent business, and other conditions make it the promised land of commercial aviation, yet even there the airlines enjoy only the undeniable promise of future prosperity and meanwhile live with the help of postal subventions and private subventions in the form of the large amounts of capital they were able to find during the last two speculative years."

This may be true, but the United States is reducing its mail contract rates, new capital is not being put into the industry, and traffic is growing rapidly and steadily. In a very few years American air transport will be an entirely self-supporting industry, which is far more than is probable in Europe.

M. Bouché has found, however, two entirely profitable airlines, both outside of

Whoa, there, You Ions...



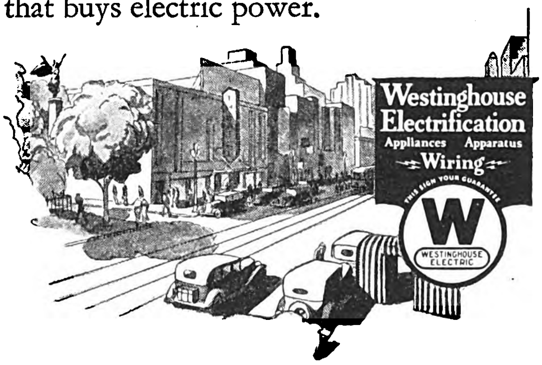
Out of the mercury arc tube — that odd-shaped bubble of glass with horns at the sides and a pool of quicksilver in the bottom — has come new light on one of the electrical industry's oldest problems.

For years research men had sought to control the arc that flashes between contacts every time a high-power electric circuit is broken. Several methods had been applied with practical results; yet the basic principles of arc formation and control remained unknown.

Then, not long ago, an engineer in the Westinghouse Research Laboratories, while working on applications of the mercury arc tube which demanded accurate arc control, concluded that the impetuous energy of any arc was due to the impetuous ions that compose it. "Harness the ions," he told himself, "and you harness the arc."

So successfully is this principle applied in the new De-ion circuit-breaker that heavy voltages can now be interrupted in open air with scarcely a flash. The electrical industry hails it as revolutionary. Important improvements are effected in a vital class of electrical equipment which the public rarely hears about—yet on which depends that smooth 24-hour-a-day flow of current now taken so much for granted.

Through discoveries and developments such as these Westinghouse research helps to give homes, industry, and transportation more value in exchange for the dollar that buys electric power.



Tune in the Westinghouse Salute over WJZ and the coast-to-coast N. B. C. network, every Tuesday evening.

Westinghouse

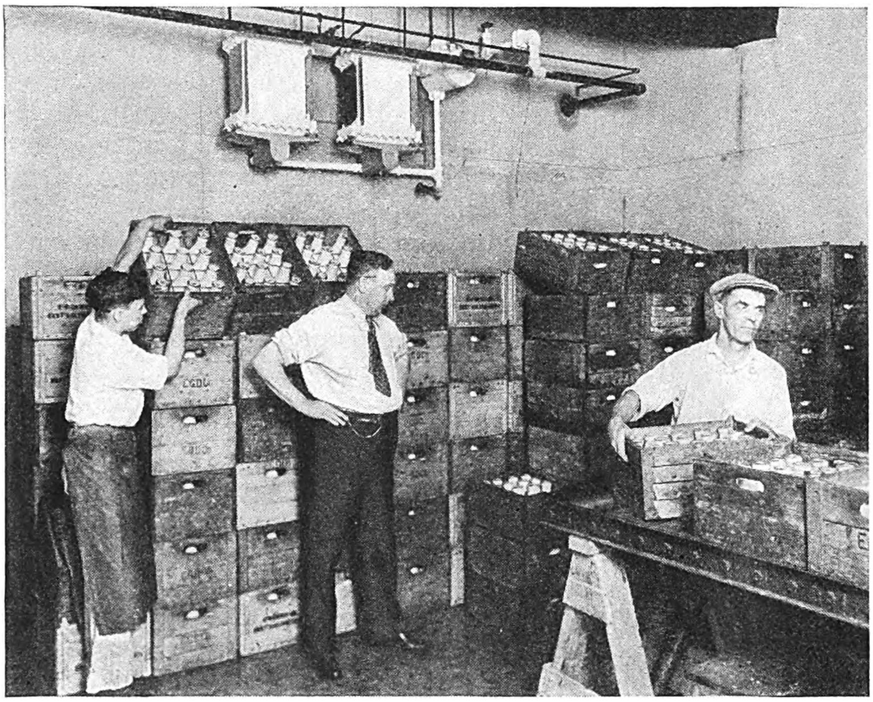
Europe and the United States. One is the German Scadta in Colombia, the other the Junkers Company in Persia. Exceptional geographic conditions enable these companies to charge what the service is really worth, namely three to six times the European air rates.

The statistics for 1929 will be very encouraging to American readers. During that year, the world had 137,000 miles of regular airways on which 2000 planes carried 600,000 passengers and 14,000 tons of freight. The United States carried 165,000, or more than one fourth of this number of passengers, and had a scheduled flying mileage of 21,000,000 while the next in rank, Germany, had only 7,000,000 flying miles during the same period.—*A. K.*

STORAGE PLANT REFRIGERATION UNIT

THE science of food preservation, which has passed through a series of marked refinements during the past few hundred years—from the days of spice application to the present era of automatic electric refrigeration—is still very much the object of the engineer's attentions.

An ingenious piece of apparatus that represents another step in the improvement of refrigerating equipment has just been perfected by the Grinnell Company. This device, known as the Unit Cooler, takes the place of the maze of pipe coils that form a regular part of the refrigeration system in milk plants, storage rooms, meat plant storage rooms, warehouse vegetable quarters, and many other commercial rooms that require conditions conducive to food preservation. The dimensions of this cooler are only 18 by 18 by 19 inches, as contrasted to the 600 lineal feet of pipe employed in the old system, and weighs but 300 pounds as contrasted to three tons of pipe coil.



A refrigerated storage room which has no maze of pipes nor any drip of condensed moisture. The automatic refrigerating unit is shown on the wall at left

With the Unit Cooler, an automatic defrosting process is carried on throughout the day. The air in the room is therefore always sweet and refreshing. In addition there is a uniformity of temperature in the room that was lacking in the old system, and that is highly desirable in a commercial installation.

The liquid refrigerant that feeds an automatic refrigeration system is controlled in this apparatus by a new device known as the liquid level control. This prevents an overfeeding of refrigerant to the system.

The small size of the Unit Cooler also makes it applicable to domestic usage. The device may be easily transported from one location to another, a feature which makes entirely feasible a system of household refrigeration and humidification comparable to some of the installations now employed so successfully in theaters and retail stores.

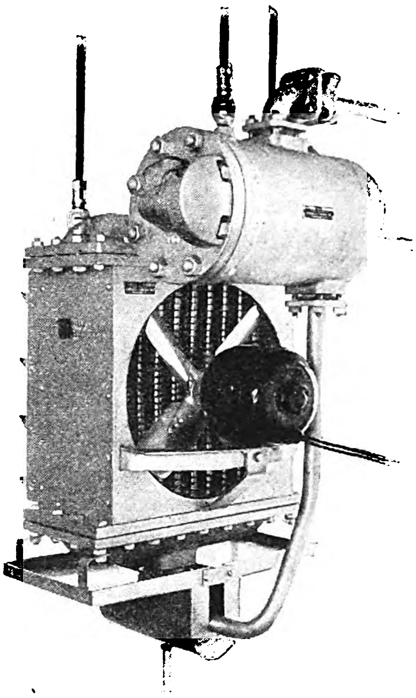
AIRCRAFT PARTS FROM SALT WATER

SALT water is the source of a metal that gives promise of playing a vital part in aircraft construction in the future. The salt brines of Michigan constitute the important raw material for magnesium production in the United States, according to John A. Gann in *Industrial and Engineering Chemistry*.

The natural brine, containing magnesium chloride, is pumped from wells 1200 to 1400 feet deep. By a series of treatments, the other salts in the brine, namely sodium chloride, sodium bromide, and calcium chloride, are removed, and the remaining magnesium chloride is evaporated to a white powder, dried, and finally fused in an electrolytic cell, where the metallic magnesium is made.

The most striking property of this metal is its extreme lightness. With a specific gravity of 1.74, it is only two thirds as heavy as aluminum, one fourth as heavy as iron and, one fifth as heavy as copper. By proper alloying and heat treatment, magnesium alloys are obtained with strength and toughness that permit them to compete successfully with other engineering metals. These properties, coupled with their high specific heat, electrical conductivity, and thermal conductivity, immediately point out many practical fields of application.

Simultaneously with the development of aeronautics has come a demand for metals with a maximum strength and minimum weight. This call was first answered by the light aluminum alloys, and now more recently by the ultra-light magnesium alloys. The more important possible applications in this field include crankcases, oil pans, seat frames, superchargers, instrument housings, control levers, impellers, and pistons. Results to date on both laboratory and flight tests indicate a big development in the forged propeller business. The properties that fit these magnesium alloys for aircraft use are their extreme lightness, high strength, and good fatigue endurance —that is, their ability to withstand repeated applications of stress.



Rear view of entire refrigerating unit showing the fan which plays a stream of air on the cooling pipes

The advantages derived from the use of light magnesium alloys are by no means limited to aeronautics. Distinct improvement in performance has been obtained when using them in many of the reciprocating parts of machinery.—*A. E. B.*

FINDS NERVES MAY CAUSE EYESTRAIN

EYESTRAIN, so-called, is more apt to be the result of "nerves" than of any disease of the eyes, Dr. George S. Derby of Boston told members of the American Medical Association at their meeting in Detroit recently. Dr. Derby described a number of cases he had seen in which the patient recovered from his eyestrain when his bodily condition was treated and when the psychologic cause of his eyestrain was explained and he was persuaded to use his eyes normally.

"If the general public could learn that

eyes are seldom strained, this would be a much happier world to live in," he said. "The fact of the matter is that the eye is provided with a large factor of safety and that healthy eyes do not become diseased even by excessive use."

Most of these cases of ocular neurosis, as Dr. Derby called it, are found in sensitive nervous persons. Fear is the commonest factor in these cases. Some ocular pain or discomfort makes the patient afraid that he is injuring his eyes permanently, that he cannot continue his occupation and perhaps will become dependent. Many of Dr. Derby's patients had given up their work and many pleasures, and were devoting themselves to resting their eyes as much as possible.

Dr. Derby asked opthalmologists not to overlook the psychologic factor in causes of eyestrain, and to treat the mental condition of their patients as well as to correct their vision with eyeglasses.—*Science Service.*

DIAMOND MATCH 9 FOR 1 SPLIT-UP

A PLAN for recapitalization of the Diamond Match Company provides for the formation of a new company with a capitalization of 1,000,000 shares of 6 percent cumulative participating preferred stock of 25-dollar par value and of 1,500,000 shares of no-par common stock, this stock to be distributed to present shareholders at the rate of five shares of preferred stock and four shares of common stock for each share held. In addition, if the plan is approved, a dividend of 25 dollars in cash will probably be declared prior to the transfer of the properties, good will, and business of the Diamond Match Company to the new corporation.

Stockholders were asked to deposit their stock with the Bank of America (N.A.) or Continental Illinois Bank and Trust Company on or before October 15.—*Barron's.*

10,000-DOLLAR RADIO IDEA CONTEST

WITH the opening, on September 25, of the Westinghouse Radio 10,000-Dollar Idea Contest, the Westinghouse Electric and Manufacturing Company extended to all America an invitation to join its cabinet designing staff. At that time, the company opened a nation-wide suggestion box with an offer of prizes totalling 10,625 dollars as an incentive for offering ideas for cabinets.

Anyone may compete except employees of the Westinghouse Electric and Manufacturing Company. The contest closes December 24, 1930, and all ideas must be in the mails before midnight December 24. The winners will be announced January 19, 1931.

The rewards for which those who accept the invitation and join the Westinghouse Radio "Idea Department" will compete, range from the first prize, a trip to Europe with all expenses paid or 5000 dollars in cash, to 25 prizes of 25 dollars each; and include between these limits the second prize, a 2000 dollar automobile of the winner's choice or 2000 dollars in cash; the third prize, a 1000-dollar check; five prizes of 200 dollars each; five prizes of 100 dollars each; and 10 prizes of 50 dollars each.

How to provide a RETIREMENT INCOME for yourself

Say good-by to money worries forever

THIS new Retirement Income Plan makes it possible for you to retire at any age you wish, 55, 60, or 65. You may provide for yourself a monthly income of $100, $200, $300, or more.

Suppose you decide to retire on an income of $200 a month when you are 60. Here is what you get:

1. An income of $200 a month, beginning at age 60 and lasting the rest of your life. You are assured a return of $20,000, and perhaps much more, depending upon how long you live. If you prefer, you may have a cash settlement of $27,000 at age 60 instead of the monthly income.
2. Upon your death from any natural cause before age 60, your wife or any other heir you name receives a cash payment of $20,000. Or if preferred, your wife receives a monthly income for life.
3. Upon your death from accidental means before age 60, your wife or other heir receives a cash payment of $40,000. Or if preferred, your wife receives a monthly income for life.
4. If serious illness or accident stops your earning power for a certain period, you will thereafter receive an income of $200 a month during such disability, even if it lasts the rest of your life.

How much does it cost?

A Retirement Income is paid for in small installments of only a few dollars a month. The exact amount depends on (1) Your present age (2) The age at which you wish to retire (3) The amount of monthly income you will want.

One of the great advantages of this Plan is that it goes into operation the minute you pay your first small installment. Even though you should become totally disabled, you would not need to worry. Your installments would be paid by us out of a special reserve fund.

Get this Free Book

The Phoenix Mutual Company is one of the oldest, most conservative institutions in this country. It was founded in 1851, and has assets of over 135 million dollars invested in bonds and first mortgages and other high-grade securities.

An interesting 28-page book called "How to Get the Things You Want" explains how you can provide a Retirement Income for yourself. No cost. No obligation. Send for your copy now.

***Above, left:* Fire in a lacquer dip tank and drain board, such as is used for finishing automobile parts**

***Above, right:* Foamite is being released automatically, and is starting to smother the roaring flames**

***Right:* The dangerous fire entirely subdued. This photograph was taken 28 seconds after the one at the left above**

These prizes will be awarded to those submitting the best 48 original and acceptable ideas for beautifying radio cabinets. If a winning idea is submitted by more than one person, the full prize will be awarded each contestant. All prize winning ideas will become the property of the Westinghouse Electric and Manufacturing Company.

It will not be necessary to submit drawings of the ideas one enters in this contest—a written description is all that will be required; however, sketches may be submitted if desired, in which case they should be accompanied with explanatory text. A person may submit as many ideas as he wishes; each suggestion should be on a separate sheet with the originator's name and address.

The judges for the Westinghouse Radio Contest will be: Miss Helen Koues, Director of Good Housekeeping Studio; Miss Neysa McMein, famous artist; Miss Rosamond Pinchot, prominent actress; Raymond Loewy, famed Parisian artist and designer; E. B. Ingraham, Vice-President, Times Appliance Company, Inc., New York City; and A. W. Robertson, Chairman of the Board, Westinghouse Electric and Manufacturing Company.

Contest entry blanks and leaflets giving helpful suggestions for conceiving acceptable ideas are available at any Westinghouse radio dealer's store.

Ideas should be mailed to Westinghouse Electric and Manufacturing Company, Radio Department, 150 Broadway, New York City.

TOILET WATER DERMATITIS

THE intricacies of modern civilization have brought new diseases and unusual hazards into modern life. However, the use of cosmetics seems to go back to the beginning of woman's vanity, and certainly that was the beginning of woman herself! Among the most frequently used cosmetics are toilet waters. Recently specialists in diseases of the skin have been seeing occasionally cases of unusual pigmentation or brown streaks running down the back of the neck. The cause of these unusual disfigurations was not understood until a specialist discovered the relationship between pigmentation and the use of eau de cologne.

Freund applied eau de cologne to the forearm of a boy and exposed this surface to the sun and to sea water. The boy developed inflammation of the skin with pigmentation. The investigator then asserted that the offending ingredient was chiefly oil of bergamot. He then rubbed oil of bergamot on the forearm of the boy and obtained the same result. Since that time numerous cases are being reported by physicians to whose attention they have come.

There are, of course, other instances in which the ingredients of perfumes and toilet waters produce irritations and pigmentation without exposure to sunlight. In these instances there is a special sensitivity which manifests itself immediately after the perfume is used. The oil of bergamot is, however, the substance primarily responsible for the special form of irritation with pigmentation that is now called "toilet water dermatitis."—*M. F.*

CHEMICAL TRICKS WITH SUGAR LUMPS AND LACQUER

WE were eating luncheon together the other day, a fire-prevention engineer and a mere chemist, the latter hoping to pick up some novel kink in the spectacular science of fire-fighting to pass on to SCIENTIFIC AMERICAN readers through these columns.

"Speaking of fires," said the specialist, "did you ever try to burn sugar?" And taking a lump from the sugar bowl he applied a match. The sugar melted but did not burn. At his invitation, we tried to ignite another lump with the same results.

"Now," announced our friend, impressively, "I will make a few magic passes over this same lump of sugar and behold it burns, readily, and even fiercely."

"Marvelous!" we applauded. "How did you do it?"

Pressed for the explanation, the student of conflagrations explained that he had surreptitiously touched the corner of the sugar lump to some cigarette ashes after which it immediately caught fire. Having satisfied ourselves that a tiny smudge of cigarette ash "did the trick" every time, we began speculating as to the chemical cause of its action. After some high-spun theories had been hazarded, the expert explained that any salt of potassium seems to work the same way and that the ashes induced the flame simply by virtue of the potash they contain. This seemed sufficient explanation to our informant, so we refrained from the question which we longed to ask—why does potash induce burning? We were pretty sure he didn't know why because the only explanation we've ever heard is that the potassium acts as a catalyst, promoting oxidation and combustion. And we didn't want to embarrass our friend, lest he might neglect to give us the "story" we wanted. As proof that our tact was fruitful, we reproduce herewith three exclusive views of a recent spectacular test of a modern Foamite fire extinguisher.

The conflagration was started in a large dip tank and drain-board, such as is used in automobile factories for dipping such parts as mud guards into the highly inflammable enamel. One photograph shows the blaze gaining headway and threatening the complete destruction of the "factory." In the second one, the automatic foam engine has begun to apply a blanket of thick "suds." The last one shows the blaze completely subdued, just 28 seconds after the Foamite application began.

All of which would indicate that the fire prevention engineer is adept in the magic of chemistry applied either to sugar lumps or blazing enamel.—*A. E. B.*

GREATEST AERIAL BEACON RIVALS SUN

THE Lindbergh beacon, the most powerful aerial light ever erected by man, has been installed on a tower on the Palmolive Building, 602 feet above the city streets, to guide fliers to Chicago.

Equivalent to a half inch section of the sun and hypothetically equal to the brilliance of two billion half-inch candles set side by side, the lamp has a visible light beam of 500 miles, lighting engineers declare. They point out that while two billion candles would occupy the area of a city block, this amount of light is concentrated in a 60-inch carbon lamp weighing a little more than a ton.

While the light's beam is visible 500 miles away, at this distance, because of the curvature of the earth, it is at an altitude too great for airplanes to reach. For practical purposes, the authorities estimate the greatest visible distance to be 300 miles from Chicago.

This beacon, dedicated to Colonel Charles A. Lindbergh by its donor and designer, the late Colonel Elmer Sperry, inventor of the gyroscope, is defined as a monumental product of modern electric light engineering science.

ASBESTOS INFLAMMATION OF THE LUNGS

WHILE the asbestos industry is more than 2000 years old, it has only within the past few years taken a prominent place among the great industries. With the development of the industry, physicians have begun to notice cases of extensive fibrous changes in the lungs due to the inhaling of the asbestos particles and inflammation of the lungs set up by the particles. When the material is taken into the lungs, it can be found in the tissues in the form of black particles. Similar particles are to be found in the sputum of the patient and indicate to the physician the source of the disorder. Drs. K. M. Lynch and W. A. Smith have described several cases in which these asbestosis bodies were seen in the sputum when the sputum was studied under the microscope. By the use of proper stain methods, they are given prominence. Thus there is provided for the scientific physician who is confronted with such a case a certain method of diagnosis.—*M. F.*

ELECTRICAL CONDUCTIVITY AT LOW TEMPERATURES

THE property of super-conductivity—that is, the disappearance of electrical resistance at very low temperatures—which has been discerned for lead, mercury, tin, iridium, and thallium, has been found by German investigators to apply to the carbides and nitrides of heavy metals. Thus the critical temperatures under which the resistance disappears is 9.3 degrees absolute for tantalum carbide. It appears possible

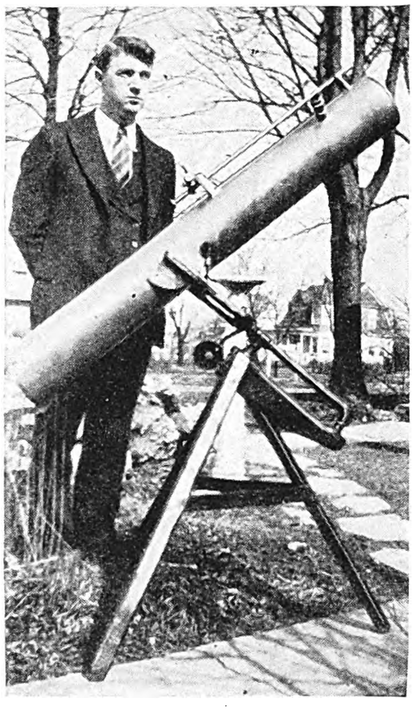
THE AMATEUR ASTRONOMER

Conducted by ALBERT G. INGALLS

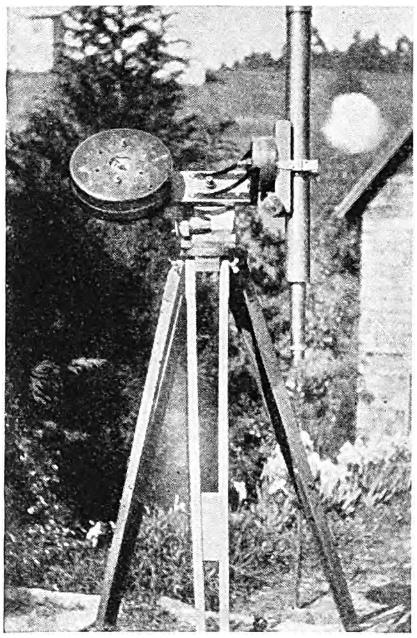
NOW that cold weather is peeking round the corner, amateurs soon will be ready to hibernate in cellar workshops, taking with them two disks of plate glass, some abrasive, and some pitch, to see what kind of a telescope can be knocked out of these "makings." This month, then, we reproduce, by way of inspiration, a number of descriptions of jobs already done by amateurs who found that the practical working instructions in the SCIENTIFIC AMERICAN book "Amateur Telescope Making" actually did instruct.

A. E. PARKE, 6453 Oliphant Avenue, Chicago, sends in a snapshot and says. "This is our first telescope which our boys and myself have just finished, a six-inch reflector which has turned out very satisfactorily. The craters on the moon and the moons of Jupiter are very distinct with a half-inch eyepiece. We have not yet had a chance at the other planets. The figuring of the mirror developed with very little trouble, and we have a total absence of color or distortion. Our mounting is made of pipe fittings on a wooden tripod and works very well. We have learned much in making this one and hope to have a still larger one."



A. E. Parke and his telescope

FRANKLIN B. WRIGHT, 155 Bret Harte Place, Berkeley, California, says: "While gazing at the Milky Way in the high Sierras I resolved to have a good portable instrument next time. The result is shown in the enclosed snapshot. It consists of a 60 millimeter (2⅜ inch) Bausch and Lomb objective costing 30 dollars, about nine dollars' worth of brass tubing and about six dollars' worth of wood, bolts and springs and other odds and ends for the mountings and tripod. Since I have no machine tools the mounting is designed to be made with nothing but ordinary tools which everybody has around the home. The bulky-looking counterweight consists of two old Chevrolet brake drums bolted together. It is adjustable in a wooden slot underneath."



Franklin B. Wright's refractor

E. LLOYD McCARTHY, 10 Powers Street, Canton, New York, a college student, sends in a photograph which shows that times have not changed since days we fondly recall; for the picture gives evidence that Sophomore McCarthy demolished a bridge in order to get a suitable pedestal for his telescope. Here is what he writes:

"The telescope has a six-inch mirror of 46-inch focal length; a one-inch prism; and a half-inch eyepiece. The mirror was polished on a lap of honeycomb foundation after failure with tempered rosin.

"That cast-iron base once did duty holding up a bridge railing. The bearings and axes are pipe fittings; the counterweight was made by casting a calculated amount of lead on a length of pipe. Two semicircular pieces of eight-inch strap iron grip the tube at its center of gravity.

"I have had some good 'shots' at four of Jupiter's moons as well as its belts; our own moon; and terrestrial objects. The other day I lectured about my telescope to one of the physics classes at St. Lawrence University, where I am a sophomore. Judging from the questions and comments afterward, about half of the class want to build telescopes of their own."

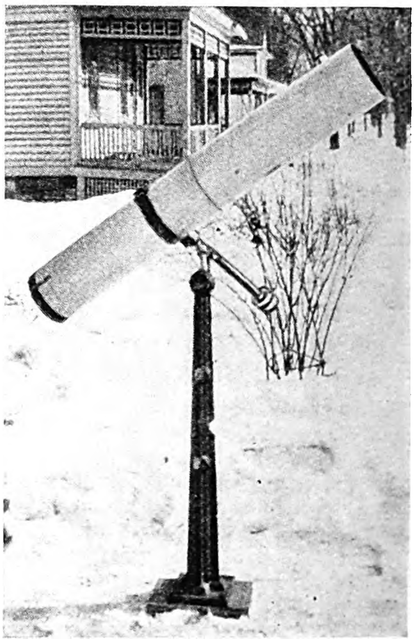
TURN now to page 71 of "Amateur Telescope Making" (the second, or 1928, edition) and you will see a telescope made by H. O. Bergstrom. Since then this enthusiast, who is a locomotive engineer at North Platte, Nebraska (P. O. Box 491), has turned out another—two more in fact, but one of the pictures he sends is out of focus so we can't reproduce it.

"Though it's a long time since you have heard from this 'T. N.' my enthusiasm in the work hasn't waned a bit," this Casey Jones (we'd like to ride behind him) writes. "I'm enclosing two photos. One of them is another six-inch reflector; the other is the eight-inch glass shown in the July 1928 number of SCIENTIFIC AMERICAN, with the mounting reconstructed. The equatorials for both these telescopes have a special 'North Platte type' quick-setting slow motion control, a real luxury for the amateur. The mount for the six-inch glass is made from an old cistern-pump stand and two Ford front wheel hubs. The other mount is made up of 'pump-stand' 1½ inch pipe fittings and two Ford transmission drums. The little 'star' standing by the six-inch glass is Marjorie Castell, aged four.

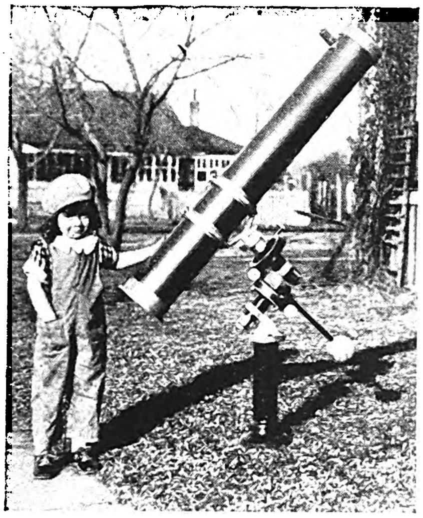
"I'm still at work on an eight-inch Cassegrain but on account of having very little leisure time the progress is slow.

"I have received quite a number of requests for a description of my earlier telescope, since it was published in the SCIENTIFIC AMERICAN. A few requests are still straggling in. Requests were received, among others, from Canada, Cuba, Australia and Java."

WRITES Paul W. Spain, 226 Seventh Avenue, North, Nashville, Tennessee: "Well, I finally got it finished. It is rather



McCarthy's "bridge type" mount



Engineman Bergstrom's telescope

crudely done, but I think it will do for a starter. The Foucault shadows were very well defined, however. I used a frosted 40-watt light in testing, and found that it gives a much better light. I was successful in my silvering the first time, probably due to beginner's luck. The tube is an old stove pipe found in a nearby junk pile.

"I am now planning a ten-inch reflector, with setting circles. The labor is certainly well repaid that is put into a telescope."

THE descriptions given above pertain to typical telescopes made by the average amateur bitten by the bug. We have on hand for publication a number of others, and these bread-and-butter jobs will be sprinkled in, as it were, with a variety of more out-of-the-ordinary things. For example there is a water-clock drive (and it actually works, too) by the old-timer Harold Lower; a telescope made in Australia; a 16-inch reflector mounted on giant sized pipe fittings; the new "milk pail" mounting discovered in Detroit; a circus telescope (Chrysanthemum our cynical office cat says they all are, but she doesn't know); a 12-inch Cassegrainian by Porter which is so smooth looking you'd want to take it to bed with you; also a 21-inch Cassegrainian by England's leading amateur, J. H. Hindle.

Jolt

your MIND out of its RUT

with this history of Man's struggle
to solve the riddles of the Universe

DO you smile at the people who thought the earth was flat? Are you contemptuous when you read how—when Galileo proved that light bodies fall as fast as heavy ones—people shrugged and called his experiments foolish?

You yourself may be just as smug about *your* knowledge of the universe. You, too, may shrug, and call impractical the calculations whereby Einstein has shattered every hallowed law of time and space.

Too many of us have let a blind spot creep into our mental outlook. We have no rounded picture of the world we live in, because we do not know what science has done and *is doing* to form our beliefs and ideas about it. And in supplying that information, this book of Langdon-Davies comes as a Jolt—an incomparable mental stimulus.

Man's struggle to solve the riddles of the universe has been his greatest adventure. In it he has suffered and died—been exiled, tortured, burned at the stake. But his thoughts have gone marching on.

The crowded, fascinating pages of *"Man and His Universe"* tell the story. They show how the facts you casually accept—the shape of the earth, movement of the planets, gravitation, evolution, atoms—came into being, and how they fell on the men and women of their days as shattering conceptions. In them, too, you will read how your own culture can be immeasureably broadened by the living, breathing procession of science's oldest and newest discoveries.

H. G. Wells, James Harvey Robinson, Richard Swann Lull—The New York Times and Tribune, the Philadelphia Ledger, etc., etc., have praised this book. Harry Elmer Barnes says, "It may work a greater revolution in human thinking than Darwinian evolutionary doctrines and their popularization. If there ever was a book which intellectual liberals should conspire to give the widest possible circulation, it is this one."

"Man and His Universe" is a book to read and to own. The coupon below makes it easy for you to get your copy—for FREE examination—at once. $5.00

HOW TO FLY AN AIRPLANE

A TEXTBOOK FOR BEGINNERS
By Percival White

GREETED by experts as unquestionably the clearest, most authoritative statement of every element which goes into the making of a finished pilot! The book is invaluable for beginners who want to cut paid instruction time to a minimum.

It explains the fundamentals of airplane construction, functions of controls, types of engines, meteorology, etc.; then puts you into an airplane, shows you how to taxi and take off, execute the various maneuvers and acrobatics, land, use parachutes, make cross-country flights, meet any emergency.

The book is aimed directly at the student's problem. Examine it FREE—use the coupon today.

Photographs and charts Price $5.00

Superlative endorsement!

"For anyone to learn to fly without it would be like taking a bath without soap!"—Capt. H. J. Loftus-Price, Editor, *Model Airplane News*.

"The most complete and thorough work of its kind. The illustrations and diagrams are splendid."—J. D. Alexander, Alexander Aircraft Co.

THE SCIENTIFIC AMERICAN DIGEST

(*Continued from page* 399)

that compounds exist in which the critical temperatures are still higher. At present this matter is entirely of scientific interest, since it does not seem to fall within the horizon of practical utilization as yet.—*A. E. B.*

FINGER NAILS IN TUBERCULOSIS

SHERLOCK HOLMES and other observant detectives remarked frequently on their ability to judge the character of the individual by his finger nails. A white line across all the nails is usually an indication that the person has been quite sick for some time.

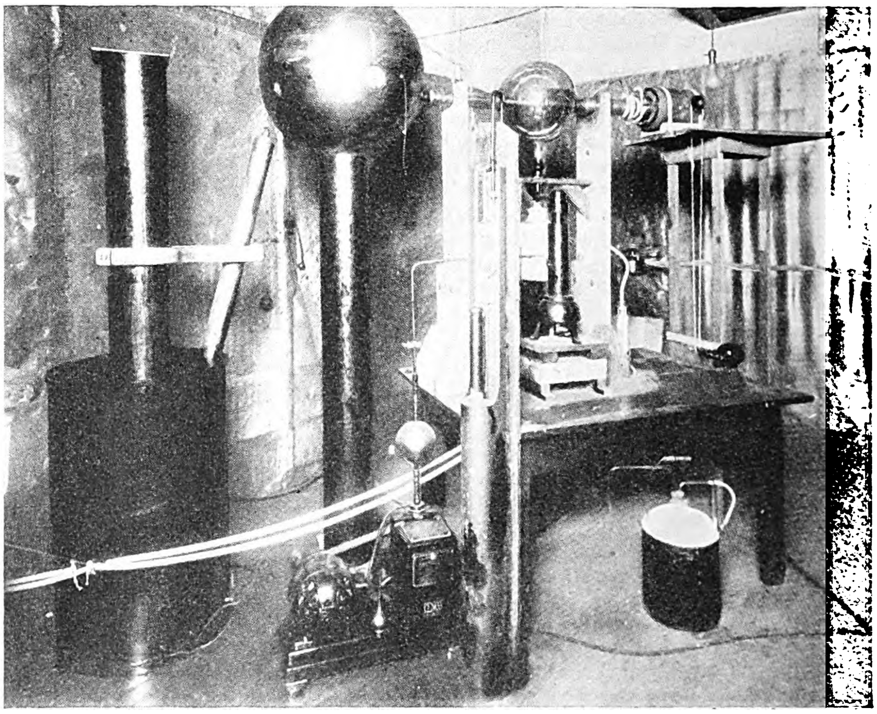
Dr. A. G. Hahn of the Trudeau Sanatorium made a special investigation of patients in that institution, and found that every one of fifty patients with active tuberculosis had pitting of the finger nails. This condition occurred in only three out of fifty patients with inactive tuberculosis, and was not found in any person who was normal. The pitting or depression appeared in the visible part of the nail about six weeks after the onset of the severe symptoms of the disease. The pits were found more often in the nails of the index and ring fingers and do not appear uniformly on the toe nails. Once the pits have appeared they naturally grow forward with the finger nail and are removed during manicuring.

More than 300 years before the Christian era, the school of Hippocrates mentioned the fact that downward curving of the nails was present in tuberculosis. Doctor Hahn found that normal people did not show such curving, 30 percent of the ex-patients had the condition, and 76 percent of the patients with active tuberculosis had downward curving nails.—*M. F.*

MAKES WELDS AIR-TIGHT BY ELECTROPLATING

AN interesting application of electrochemistry to a problem in steel welding is recounted by J. B. Calva in a recent issue of *Chemical and Metallurgical Engineering.* In building a tubular evaporator, the tubes were welded to the headers by the electric process, but on testing it was found that while the joints were mechanically strong, they were not air-tight, because of the presence of many minute capillary tubes produced by the electric arc.

Since this particular evaporator was intended to operate under a vacuum, it was necessary to make these welds air-tight. Caulking the joints proved vain. The next experiment was to induce the clogging of the capillaries with rust by promoting oxidation in their walls with a solution of ammonium chloride. This treatment also failed. Finally, a permanent remedy was applied. Around each of the welds, and concentric with the tubes, rings made of round structural iron, ¼ of an inch in diameter, were placed. These rings were held in place and insulated by means of small pieces of rubber which were compressed between the iron rings and the projecting ends of the tubes. The rings were then interconnected by means of copper wire and a water-tight wooden cover was



Recent experiments by Prof. J. S. Long of Lehigh University may procure for linseed-oil paint the same quick-drying properties as modern lacquers. The work has been conducted with the huge cathode-ray machine illustrated above. The rays from this tube were focused on samples of linseed oil for various periods and it was found that paint made from oil that had been "bombarded by electrons" for 10 minutes dried in half the time required for ordinary paint. The photograph shows the cathode-ray machine adapted for further experiments on the so-called drying oils. It is placed in a special room, the walls of which are completely covered with sheet lead to prevent the escape of the cathode rays

bolted to the flange. A piece of copper wire connected to the rings was made to pass through a rubber stopper which fitted a hole in the wooden cover.

An electrolyte made up of ferrous chloride, calcium chloride, and water was then poured into the tubes and in such an amount as entirely to keep immersed in it all the iron rings and welds. The electrolyte was kept as hot as possible by means of a steam coil.

The electric welding machine was then adapted for electroplating work by inserting in the magnetic field of the generator a slide-wire resistance. This was done in order to reduce the voltage at the terminals of the generator so as to limit the current to a density of 15 to 20 amperes per square decimeter, calculated on the effective surface of the iron rings.

The positive terminal of the generator was then connected to the copper wire coming from the iron rings and the negative terminal to the evaporator. After 24 hours of electro-deposition of iron on the welds, the evaporator was tested and the maximum expected vacuum was obtained. —*A. E. B.*

USE FLUE GAS TO PREVENT DUST EXPLOSION HAZARD

So many forms of dust are highly explosive that methods of preventing this hazard have long engaged the attention of chemists in the United States Bureau of Agriculture. One of the expedients they have developed is the use of an inert gas as the atmosphere to surround grinding operations and others that are apt to produce dangerous dust.

Such installations have been made at two hard-rubber grinding plants, a cork grinding mill, and a pyrethrum-flower grinding plant. A number of sulfur-grinding mills have adopted this method of preventing explosions, and a feed-grinding plant in the middle west is now installing one of the largest inert-gas systems in the country. The use of inert gas to provide protection in one of the large starch plants is being considered, and experiments are under way to develop methods of properly cleaning and conditioning the gas for such use. Fire extinguishers filled with inert gas under pressure, instead of chemicals, are now being produced and are finding a ready market in this country.

Methods of cleaning and conditioning flue gas to render it satisfactory for use as a preventive of dust explosion and fires are now being developed.—*A. E. B.*

SPRAY PAPER MULCHES TO AID CROPS

The use of mulch paper for covering the fields between furrows in order to help the soil retain moisture and to prevent the growth of weeds has been described previously in these columns. An interesting variation of this new idea is being tried out in Germany. Instead of covering certain crops with paper sheets, as is customary in America, a paper coating is sprayed on the fields.

The action of paper coverings results in many cases in a greatly increased production of certain crops, because the soil temperature is increased, weeds suffocated, pests destroyed, and the soil bacteria activated. The paper spray is said to be cheap, cannot be removed by the wind, and is not dissolved by rain. Its most obvious advantage over the use of paper in sheet form is its ease of application. What the effect on the growing plant will be has not yet been determined.—*A. E. B.*

PNEUMONIA FROM INHALING GASOLINE

Experimenting, boylike, with a rubber tube and the gasoline tank of an automobile, an eight-year-old lad got an unexpected dry cleaning of his lungs, which resulted in pneumonia, when his companion blew on the other end of the tube. The case was recently reported to the American Medical Association.

When the other end of the tube was blown into, the gasoline was forced into the boy's mouth. He choked and had a severe strangling spell, from which he recovered, but pneumonia developed. For four weeks he could taste gasoline and it could be smelled on his breath.

Gasoline is rapidly absorbed by the lung tissue, the report stated. The pneumonia that follows this absorption is not typical. The fever is not high and the rapid breathing continues for a long period. The inflammation of the lungs does not remain in one spot, but wanders about, suggesting that the gasoline fumes also wander about in the lung tissue, setting up inflammation in other spots.—*Science Service.*

TIMING A FLASH OF FLAME

The factors that contribute to the propagation of explosions in gaseous mixtures are being studied by the United States Bureau of Mines. This is part of the Bureau's investigation of the mechanism of mine explosions. No matter how long the column of an explosive gas mixture may be, the speed of the flame, when initiated, is accelerated rapidly until it reaches a maximum and constant velocity. The term "detonation" is applied to this type of explosion. So fast does the flame front travel that it sometimes reaches the high value of 10 times the velocity of sound, or over two miles a second.—*A. E. B.*

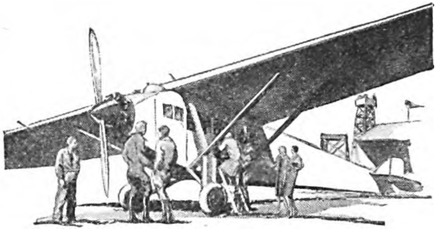
NEW PRODUCT PRESERVES AND IMPROVES GLUE

When the organic chemist begins to juggle atoms, tacking one here and another there on some molecule with a mouth-filling name, no one, including himself, knows what kind of a substance is going to result or what use it may prove to have. Thus, during the past year, chemists of the Dow Chemical Company, Midland, Michigan, have developed, from the laboratory stage to actual commercial production, a new product known as orthophenylphenol. Now what is this substance good for?

Well, being a relative of carbolic acid, one might suspect that the newcomer would be useful as a germicide, but we'll give you 999 guesses as to where it has found application. Answer: In making glue!

The problem of glue preservation, both from the standpoint of preventing mold and that of eliminating putrefaction, has been of extreme importance to both glue manufacturers and glue users. The sodium

"how can I get into Aviation?



Read this Answer from

A World Famous Trans-Atlantic Pilot

AVIATION is waiting for no one! Landing fields, plane and equipment factories, air lines, service and sales organizations—all are leaping ahead in the most amazing development any industry has ever known. In such racing, feverish activity, *where* is there any room for a man who has nothing to offer? An empty pocketbook is no drawback—but Aviation has no place, no patience, no *time* for empty hands or empty heads! The men who will climb to the top are the men with a foundation of FACTS under them.

You Don't Have to Fly; 40 Different Jobs on the Ground. PAY BIG, too!

To succeed in Aviation—make BIG MONEY—you don't need to be a pilot. There must be thousands of pilots, certainly. But for every plane that flies, there's an immediate need for trained men in more than *forty* different important jobs on the ground. Construction, motor and instrument experts—airport managers, service foremen, salesmen—and more all make *real* money. But every last one of them must have the FACTS. Today's problem—YOUR problem—is to LEARN Aviation *quick.*

Get Your Ground Work at Home
YOU can train at home in spare time. Hinton's proved course gives you *all* the facts about construction, motors, instruments, theory of flight, navigation, commercial Aviation—facts that every man must have to fill ANY job in the Industry. Hinton also helps you get your start; helps you get a job with a real future. *Air-minded* men are reading and acting on the Free Book shown below. Send the coupon NOW.

Walter Hinton

was pilot of the famous NC-4, first plane to fly the Atlantic. He piloted the first plane from North to South America. He was first to fly to the headwaters of the Amazon. During the War he was a crack flying instructor for the Navy. Today he is training keen-sighted men for Big-Pay jobs in Aviation.

Bill for first operation performed under ether in 1842

IF YOU read "The story of Anesthesia" by Dr. John H. Evans in the November issue of HYGEIA, the Health Magazine, you may pause at the tale about the above bill and say, "Them was the good old days". But that first rude experiment is a far cry from the perfected science of anesthesia as surgeons administer it today. At some time in your own life, either because of an operation on yourself, a member of your family or a friend, you will be personally interested in some kind of anesthesia. Read Dr. Evans' story of ether and laughing gas in the "good old days". Let him tell you about the wonderful development of perfected anesthetics in "these still better days". Let him put you right regarding the various kinds of anesthesia.

"PHYSICAL ILLITERACY" what is it?

Do you get your exercise listening to the base-ball reports over the radio or sitting in the bleachers watching a football game? This form of exercise is so common to all Americans that it has been given a name—"Physical Illiteracy". Dr. J. E. Rogers points out the grave danger of physical illiteracy upon your individual health, the health of your family, community and country. Read this article in the November HYGEIA.

OTHER VITAL HEALTH ARTICLES in the November HYGEIA

"Perception" by Dr. William J. Mayo; *"April Blue"*, a child's health story; *"How to Protect Your Children from Tuberculosis"*—these are only a few of the additional health attractions treated in the November HYGEIA. The articles in HYGEIA are written by health authorities in a charming, non-technical style, pleasing to the layman, who can be sure that the variety of health topics presented are scientifically true. HYGEIA is for every member of the family. Take advantage of this special introductory offer to get acquainted with HYGEIA. The regular subscription price is $3.00 a year, but new subscribers are offered the special get-acquainted-price of $1.00 for six months.

salt of this phenol is water-soluble in all proportions and, regardless of its high phenol coefficient, is reported by bacteriological laboratories as being non-toxic to humans. The quantities necessary to use are exceptionally small; 0.5 percent of sodium orthophenylphenate by dry weight has proved in all tests a complete control against both mold and putrefaction.

The measured strengths of glue have shown that in quantities from 0.1 percent to as high as 5 percent, sodium orthophenylphenate has in all cases increased the strength of the glue and at the same time has given it a slightly bleached effect which is considered very desirable.—*A. E. B.*

"GALAGUM"

GALAGUM is the name given to a mixture of modified polysaccharides recently introduced and described in *Industrial and Engineering Chemistry*. It is a white powder, tasteless and odorless, and acid in reaction. It can also be obtained in a neutral modification. Galagum, when boiled in water, forms colloidal solutions of different viscosities, depending on concentration. A 1 percent solution forms a syrupy solution, a 5 percent solution forms a paste or jelly.

Neutral Galagum is edible and is used in making bakers' and flavoring emulsions. In the cosmetic industry viscous aqueous solutions are much used in lotions and hair preparations. These are produced by dissolving 1 to 4 parts of Galagum in 100 parts of boiling water.

In the baking industries it has been found that neutral Galagum replaces part of the eggs ordinarily used. In the manufacture of ice cream, neutral Galagum decreases the amount of gelatin required. Certain cheeses which are made with various protective colloids to give them smoothness and body may likewise be made with neutral Galagum.

Technically, Galagum possesses interesting properties in that it may be used for giving a heavier body to water paints, sizes, glue, and many other aqueous solutions. —*A. E. B.*

RESPONSIBILITY FOR TYPHOID FEVER

TYPHOID fever is carried principally by contaminated food and water and by carriers of the disease whose excretions get into food and water. From time to time brief epidemics have occurred in this country due to the fact that sewage has gotten into the water supply. An epidemic occurred in Salem, Ohio, several years ago, when there were several hundreds of cases. Small epidemics have also occurred in factories where the drinking water became contaminated by sewage.

In Lyons, France, recently the court held the water company responsible for the illness and death of various citizens who had become infected with typhoid fever from contaminated water. Moreover, the court declared Mr. Mercier, director of the water works, to be guilty of involuntary homicide as a result of his imprudence, negligence, and infraction of the regulations. They sentenced him to one year in prison, with suspension of execution, and they fined him 500 francs. Some of the people who developed typhoid fever were awarded damages ranging from 20,000 to 100,000 francs.

The epidemic originated from two wells which were contaminated by the water of a sewer. In its decision, the court maintained that it is the duty of the water distributing company to guard the purity of the water that it distributes. The monthly analyses made by the company were inadequate, and the company should not have ignored the dangers associated with the proximity of a sewer to the water supply.—*M. F.*

VARIATIONS IN SUSCEPTIBILITY TO DISEASE

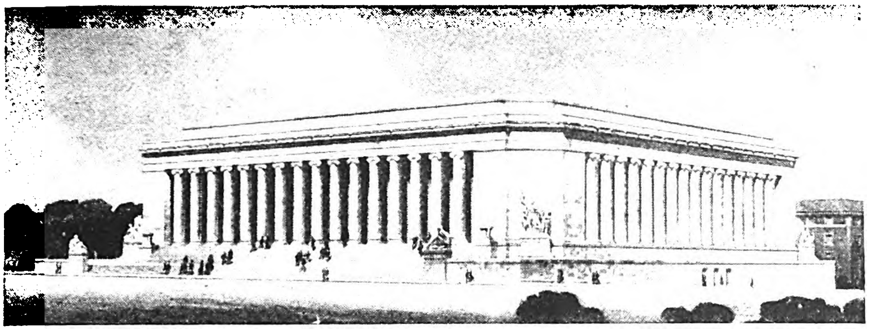
IT has long been known that different races vary in their susceptibility to various disease. Centuries of infection with syphilis have made the Chinese relatively insusceptible to that disorder. Jewish people suffer less than other groups from alcoholism and tuberculosis, whereas they suffer particularly with diabetes and with a disease of the arteries known as thromboangiitis obliterans. The races of Africa and the South Sea Islands have been free for many years from such conditions as measles, but come down with serious epidemics from the disease when it is introduced among them. For some unexplained reason scarlet fever is rare in the tropics; although cases have repeatedly gone into India, South America, and the Philippines, the result is only a local epidemic largely confined to newly arrived foreigners and with few cases developing among the local population. Several investigators have attempted to find out the reason for this immunity, and the most recent evidence indicates that this is due to some hereditary factor.

For instance, the Chinese are relatively free from scarlet fever as compared with the Japanese. Of 11,000 healthy Japanese tested, 37.3 percent were found positive to the Dick test, which was about the same percentage as reported by Zingher for New York City. On the other hand, only 19.4 of 3500 Chinese were found to be Dick positive. For a period of six years, the annual scarlet fever mortality among the Japanese was 361 per 100,000, as contrasted with 8 per 100,000 for the Chinese. —*M. F.*

HYBRID PLANT YIELDS PAPER AND OIL

BROTEX, a newly developed plant which threatens to replace hemp and to supply a suitable raw material for the manufacture of paper, is attracting considerable attention among British chemists. The new plant is being grown in America, France, Germany, Kenya, and Canada, as well as in the British Isles, and its possibilities on a wide range of soils are interesting great numbers of scientists and agriculturists.

Experimental work which has been already carried out indicates that it is a sufficiently hardy plant to be grown successfully to yield a six months' fiber crop in many parts of England and in other countries. In its six months and later stages the plant produces fiber which can be used for sacking, cordage, ropes, and the products in which coarse hemp is usually employed. For paper-making it affords a very quick-growing material. Its seed can



The new home of the Mellon Institute as it will appear when finished

be used for cattle food in the form of oil cake having 15 percent edible oil.

The plant, which is a hybrid biennial, was produced after many years of experiment by Mr. Leonard Browning. No extravagant claims have been made for it, and the closest scientific research is still being carried on.—*A. E. B.*

NEW HOME TO BE BUILT FOR MELLON INSTITUTE

ONE of the most interesting places in the world to anyone interested in chemistry is the Mellon Institute in Pittsburgh, Pennsylvania, and one of the most interesting of all chemists is its director, Dr. E. R. Weidlein. The fascination of the great laboratory and its director are both due, in part, to the fact that their work keeps them about two jumps ahead of the innumerable applications of chemical engineering to industry, for the Mellon Institute is the scene of hundreds of scientific conquests that later find their way to the public in the form of improved products.

Manufacturers, groups of manufacturers in similar fields, and even trade associations establish fellowships at the Institute, making it possible for some highly trained chemist or engineer to concentrate on the particular technical problems that they are most anxious to have solved. At the present time there are 63 industrial fellowships, relating either directly or indirectly to almost any business that can be named. Now Director Weidlein announces that a monumental new home for Mellon Institute, illustrated herewith, will be started this fall.

When the present home of the institute was completed, in 1915, it was felt that the industrial fellowships procedure created by Robert Kennedy Duncan had passed from the experimental to the practical stage. The building, which was given to the Institute by Andrew W. and Richard B. Mellon, incorporated the best laboratory constructional features of that period. It was thought then that it would provide adequate space for growth for many years; but for practically 10 years the institute has had a waiting list of companies, often almost as long as the roster of companies whose problems were being investigated.

In addition to providing a greatly increased number of laboratories, the new building will give more commodious quarters for general departments. The present library contains 11,000 volumes; the new library is planned to accommodate 250,000 volumes. The present Department of Research in Pure Chemistry will be expanded and facilities for pure research in other branches of science will be provided. Much more elaborate chemical engineering laboratories are to be available in the new building, and also the fellowships in each specific field of industrial research are to be grouped in suites of rooms so that they can best make use of general apparatus adapted to their needs. Certain rooms will be equipped for specialized phases of experimental technique, such as electrochemistry, spectroscopy, low-temperature studies, radiations, high-pressure experimentation, and so forth. Other special features to be included are a large lecture hall, a dining hall, an industrial fellowship museum, and an underground garage. For the past five years, members of the institute's executive staff have been visiting laboratories in America and Europe to obtain information on new features in design and equipment.

The new laboratory structure will be of that type of classical Greek architecture known as Ionic. It is to be seven stories high, with monolithic columns along all four sides. The proportions will be approximately 300 by 400 feet. The main entrance, which is located on the third floor, is reached by steps extending along the entire front of the building. The laboratories are to face on interior courts. The design of the new building is to be such that additional laboratory suites can be constructed in the interior courts without marring the beauty of the general appearance and without interfering in any way with the original laboratory units.—*A. E. B.*

BASEBALL PITCHER'S ELBOW

WHEN a baseball pitcher winds up to pitch a ball, the arm and forearm should be held in extension and the throwing of the ball should be from the shoulder. Sometimes, during the wind-up, a pitcher will hold his arm slightly flexed; then as he prepares to throw the ball, by suddenly and forcibly contracting the muscles in the back of the arm and rotating the forearm and hand inward and downward to give speed to the ball, he extends his forearm rapidly. In the maneuver the head of the large bone of the forearm is brought backward suddenly and with great force against the large bone of the upper arm. As a result, a small piece of cartilage and bone from the head of the radius, the large bone of the forearm, may be chipped off, will remain about the joint, and be constantly irritating and troublesome with every movement.

The average velocity of a baseball after it leaves the pitcher's hand is about 90 feet a second. This will give some indication of the force involved in the production of this injury.

Dr. F. J. Kirby has reported two cases

FACTORS IN THE SEX LIFE OF 2200 WOMEN

By Katharine Bement Davis, Ph. D.

This pioneer volume offers concrete factual data on the events in the sex life of normal women, supplying needed information on a topic which has long been the subject for uninformed conjecture.

Under the expert direction of Dr. Davis, two groups of selected women—married and unmarried—replied anonymously to questionnaires designed to elicit information on every phase of woman's sexual life. Full data on the various periods of life, as well as on so-called "abnormal" experiences were received.

This information was first tabulated. Then comparative statistical studies were made on the most important topics. The book offers specific data on many questions like: What factors seem to enter into the "happy" and "unhappy" married life? What are the causes and extent of abnormal practices? What is the importance of sexual education, etc.?

The clear and simple treatment makes the book invaluable to social workers, physicians, parents, educators; first in developing a saner attitude toward the whole subject; second as a tested method in throwing light on sexual maladjustments as affecting personal relations.

The Scientific American says: "Almost to a certainty this book will upset a number of fondly cherished beliefs. It is a thoroughly scientific record of scientific work in sociology, performed by a noted scientific authority. The discoveries recorded were based on actual data secretly obtained." For free examination, use the coupon now. Price $3.50.

of this character which came to his attention. In both, unfortunately, it was necessary to open the joint and to remove the small piece of bone in order to relieve the patient from constant difficulty in movement. Just as soon as the loose portion of the bone is removed and the operation wound heals, the patient is likely to recover fully.—*M. F.*

400 TONS OF BOTTLES A DAY

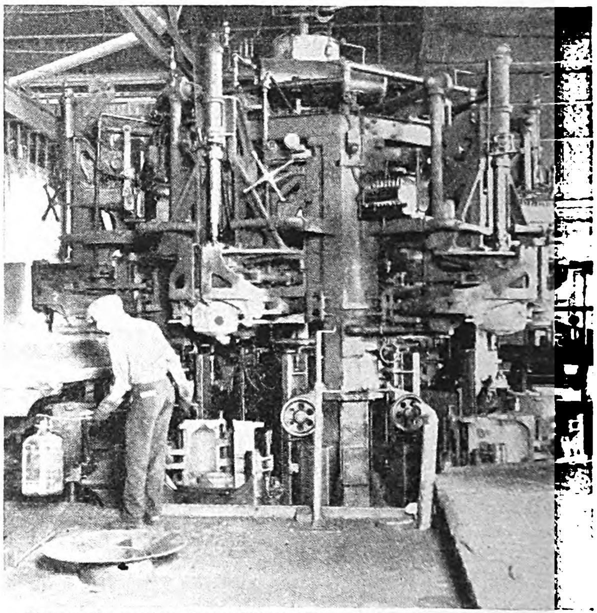
GLASS bottles! How often they play their unobtrusive rôles in little dramas of modern life: The message floating at sea in a stoppered bottle; the tiny vial of serum rushed to save a life; the "pop" bottles at the ball park and the road stands; the daily milk bottles; the bottles that gleam in the chemists' laboratory, on the barber's shelf, in the drug store, the grocer's, the stationer's. It is hard to realize how completely our comfortable modern life would be disorganized if glass bottles were suddenly taken away from us.

Until comparatively recently, all glass bottles were blown by hand or, rather, by mouth. A "gob" of molten glass was balled around the end of a blow pipe, by a skilful glass blower, and the bottle blown by lung power into a mold which gave it the desired shape. The demand for more and cheaper bottles has spurred the glass technologist and the mechanical engineer to convert the age-old process to a highly refined machine operation, until today, we find at Alton, Illinois, a single factory which produces 300 tons of machine-blown bottles per day. The bottles produced here by the Owens-Illinois Glass Company include over 3200 different styles and sizes.

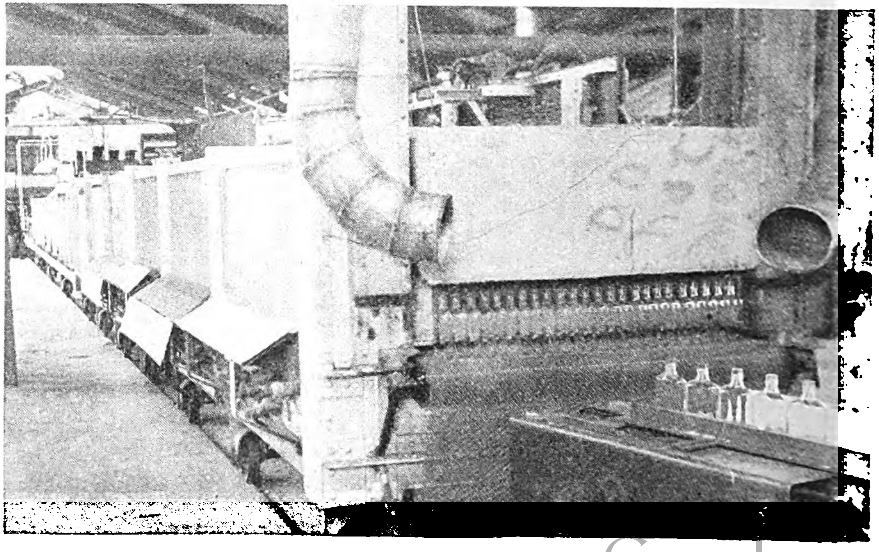
The molten glass fed to bottle machines must be exactly right in composition. Expert chemists control every step in its manufacture. In addition, finished bottles are inspected with instruments so delicate that the internal strains set up in the glass by holding a lighted match near the bottle can be readily discerned.

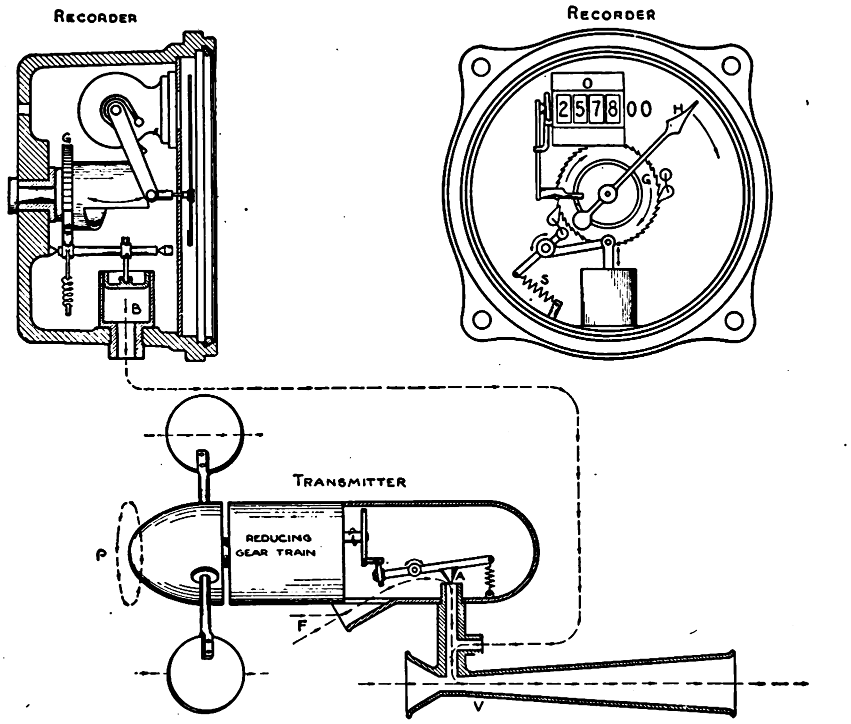
In the research laboratory of the company there is a collection of instruments not frequently found in an industrial laboratory. Among them is a specially constructed precision interferometer which is used in detecting sub-microscopic cracks in glass. An Abbe-Fizeau interferometer, regularly applied to the determination of the coefficient of expansion of glass, has been specially modified to adapt it to the determination of the softening point and heat conductivity of glass in addition to its regular function. The study of the structure of complex silicates is aided by means of an X-ray reflection apparatus. A precision Ruprecht

Right: Largest bottle blowing machine in the world. It is a six-head, vacuum-feed type, standing 20 feet high and weighing 120 tons. The revolving pot of melted glass is just to the left of the attendant who is removing a five-gallon carboy from its mold. *Below:* The feed end of an electrically heated lehr, in which the bottles are annealed



Photographs courtesy Owens-Illinois Glass Company





This new air log indicates airplane miles traveled

balance is used to determine slight losses in weight due to the solubility of glass, whole bottles being used in the experiments.

Machine-blown bottles furnish a striking and dramatic example of the mechanization of an ancient industry, made possible by the combined genius of scientists and engineers.—*A. E. B.*

USE OF ELECTRICITY DOUBLED

PER CAPITA use of electric power in the United States has more than doubled in the last ten years, according to statistics based on the 1930 census, says F. E. Bonner, executive secretary of the Federal Power Commission.

The figures show that for the entire country, the per capita use increased from 391 kilowatt-hours in 1920 to 800 kilowatt-hours in 1930.

THE AIR LOG

THERE is nothing more interesting on board ship than to lean over the taffrail and watch the log do its endless work of recording distance. The corresponding aircraft instrument, the air log, is less frequently employed. Its greatest value lies in long flights as an aid to navigation. It is also very useful for such records as fuel and oil consumption, mileage between overhauls, and other data of interest to the transport operator. The air log or air distance recorder as now built by the Pioneer Instrument Company, is an ingenious and interesting mechanism.

It consists of two parts—the transmitter and the recorder. In a biplane, the transmitter is mounted on one of the outer interplane struts, while on a monoplane it is mounted three feet or more ahead of the leading edge of the wing, so as to be free to some extent of the air-flow disturbance caused by the wing. The recorder is mounted on the pilot's instrument board. The two units are connected by a small copper tube. The basic principles of the recorder are clearly illustrated by the accompanying drawings.

The flow of air through the venturi tube V causes a suction at its throat or narrowest section, where the air must flow with its greatest velocity. This suction is carried through the copper tube to the piston B in the recorder, and pulls down the piston B against the action of the spring S.

The flow of air, as the plane moves forward, also rotates the flat disk propeller P, in the direction shown by the circle and arrows. The pitch of the propeller and the ratio of the gear train in the transmitter are such that the valve A is opened once every mile. This allows air to flow in at F and breaks the suction in the line. Once the suction is broken, the spring S pulls the piston B up to the top of its stroke, the position shown in the drawing. Simultaneously this causes the pawl to move the gear G one tooth, carrying the hand H on the recorder dial one unit forward. Valve A is then closed and the piston is once again sucked to the bottom of the cylinder ready to repeat the action at the end of the next mile.

The gear G has 100 teeth so that the hand makes one complete revolution for every 100 miles traveled. The gear also rotates a spiral cam causing the counter arm to move and indicate another hundred miles while the hand H continues on the next revolution. Total mileage flown is obtained by adding those shown by the counter and the hand. The mileage for a given trip is obtained by noting readings at the start and end of the trip.—*A. K.*

A NEW PORTABLE POWER UNIT

A PORTABLE electric power plant, weighing 120 pounds and capable of delivering 1000 watts, has been developed by the Westinghouse Electric and Manufacturing Company. This plant is provided with duralumin skids which make it easy to transport. It is powered by a gasoline

The portable power unit described below

engine developing two horsepower at 4000 revolutions per minute.

There is only one exposed moving part. All other parts are enclosed in a sealed bath of oil, protected from dust and dirt. The gasoline tank has a capacity of 2½ quarts which is sufficient to operate the engine for three hours under full load conditions. The engine speed is controlled by an automatic mechanical governor. Accurate speed adjustment is provided between 1800 and 4000 revolutions per minute.

This portable plant has been designed to meet the needs of construction and repair crews for a convenient and portable source of power. It is ideal for use in the field where power is required for drills, chisels, saws, and similar tools.

CURRENT BULLETIN BRIEFS

SHORT REVIEWS OF BULLETINS AND PAPERS ON SCIENTIFIC AND ALLIED SUBJECTS, AND WHERE TO GET THEM

HYDRO-ELECTRIC POWER COMMISSION OF ONTARIO, REPORT FOR 1929 is an important treatise on co-operative municipal-ownership power enterprises. Practically the whole province of Ontario is being supplied with Niagara Falls power at cost. There are excellent maps and a wealth of data. *Hydro-Electric Power Commission of Ontario, Toronto, Canada.—$2.00.*

◆

GEOLOGY AND WATER RESOURCES OF THE KAU DISTRICT, HAWAII (U. S. Geological Survey Water Supply Paper 616) is a misleading title, for the pamphlet is mainly descriptive of the geology of Mt. Kilauea where Dr. T. A. Jaggar maintains the United States Volcano Observatory. *Superintendent of Documents, Washington, D. C.—85 cents (money order).*

◆

BOOKLIST BOOKS 1929, A SELECTION, gives the most important list of the new books giving brief notes as to their value together with the number of pages and the prices. It is accompanied by a complete index. *American Library Association, Chicago.—65 cents.*

◆

AERONAUTICS TRADE DIRECTORY (Aeronautics Bulletin No. 3, Aeronautics Branch, U. S. Department of Commerce) is a most valuable booklet dealing with commodities and activities. It gives a complete list of manufacturers of airplanes, accessories, airport designers and constructors, engine manufacturers, hangar builders, and all the thousand and one items that go into this industry. It also gives a complete list of air-transport operators and aeronautical engineers. *U. S. Department of Commerce, Aeronautics Branch, Washington, D. C.—Gratis.*

◆

NATIONAL PHYSICAL LABORATORY REPORT FOR 1929 is a 300-page book giving a description of a year's research at Great Britain's "bureau of standards." It deals with heat, radiology, sound, optics, electricity, measurement, and general research. *His Majesty's Stationery Office. London, England.—Eleven Shillings.*

◆

THE ATMOSPHERE AND THE SUN (Smithsonian Miscellaneous Collection, Vol. 82, No. 7 by H. Helm Clayton) gives further scientific evidence of weather cycles, their causes and interpretation, with a particular view to long-range weather forecasting. *Smithsonian Institution, Washington, D. C.—25 cents.*

◆

EARLY PUEBLO RUINS IN SOUTHWESTERN COLORADO (Bulletin No. 96, Bureau of American Ethnology, Smithsonian Institution) by F. H. H. Roberts, Jr., is a 180 page account of archeological work done in 1928, with a brief history of early American cultures. Illustrated. *Superintendent of Documents, Washington, D. C.—75 cents.—Money order.*

AUTOMATIC ARC WELDING BY THE ELECTRONIC TORNADO PROCESS is a monograph on an accepted method for manufacturing pipe, tanks, boilers, and similar equipment when the production is sufficiently large to justify the cost of equipment. *The Lincoln Electric Company, Cleveland, Ohio.—Gratis.*

HINTS ON COYOTE AND WOLF TRAPPING (Leaflet No. 59, U. S. Department of Agriculture), *Superintendent of Documents, Washington, D. C.—5 cents, coin.*

MODERN METHODS IN REPAIR SHOPS is a large and beautifully illustrated monograph of 120 pages dealing with cranes, turn tables, car washers, and other devices useful in car shops, roundhouses and terminals. Free to interested parties. *Address Whiting Corporation, Harvey, Illinois.*

THE SURFACE WATERS OF MICHIGAN (Engineering Research Bulletin No. 16, Department of Engineering Research, University of Michigan) by Robert L. McNamee, outlines the hydrology and qualitative characteristics and purification of water for public use. Accompanied by an excellent series of maps. *Department of Engineering Research, University of Michigan, Ann Arbor, Mich.—$1.50.*

THE INDUSTRIAL MUSEUM OF NEW YORK describes an exhibit of early astronomical and mathematical instruments. It also describes the David Eugene Smith collection and contains a monograph on the Astrolabe by Jekuthiel Ginsburg, A.M., and on (Sun) Dialing by J. Ernest G. Yalden. *Museum of the Peaceful Arts, Daily News Building, East 42nd St., New York City.—Gratis.*

THE HIGH SCHOOL SCIENCE LIBRARY FOR 1929-30 by Hanor A. Webb gives the titles of the very newest books in the field of science on the junior and senior high school level. *Address Hanor A. Webb, George Peabody College for Teachers, Nashville, Tennessee.—10 cents.*

CONSERVING VISION IN INDUSTRY (Publication No. 68) contains several interesting signed papers. *The National Society for the Prevention of Blindness, 370 Seventh Ave., New York City.—25 cents.*

FORMATION AND PROPERTIES OF BOILER SCALE (Engineering Research Bulletin No. 15, Department of Engineering Research, University of Michigan) by Everett P. Partridge, is an elaborate discussion of the subject, accompanied by a full bibliography. *Department of Engineering Research, University of Michigan, Ann Arbor, Mich.—$1.00.*

SAFETY CODE FOR BRAKES AND BRAKE TESTING (Miscellaneous Publication No. 107, Bureau of Standards, Department of Commerce) gives valuable results which have been approved by the American Standards Association. *Superintendent of Documents, Washington, D. C.—5 cents, coin.*

SPICES AND CONDIMENTS (Leaflet No. 15, Field Museum of Natural History, Department of Botany) by James B. McNair, Assistant Curator of Economic Botany, is a valuable pamphlet fully illustrated and gives much out-of-the-way information. *Field Museum of Natural History, Chicago, Illinois.—25 cents.*

THE RUN OF THE TWENTIETH CENTURY, by Edward Hungerford, is one of the most illuminating publications on railroad service we have ever seen. It is accompanied by excellent diagrams and illustration. *New York Central Lines, 466 Lexington Avenue, New York City.—50 cents.*

THE CARNEGIE FOUNDATION FOR THE ADVANCEMENT OF TEACHING gives valuable information as to retirement and pensions. *Carnegie Foundation for the Advancement of Teaching, 522 Fifth Avenue, New York City.—Gratis.*

ARTIC, THE REFRIGERANT (Technical Paper No. 274) is a small treatise on the physical properties and performance data of Artic. Of value to anyone interested in refrigeration. *The Roessler & Hasslacher Chemical Co., Niagara Falls, N. Y.—Gratis.*

OUR POINT OF VIEW

(*Continued from page* 349)

of our Navy as a matter of course; actually it is the result of generations of systematic effort. The naval routine which trains American lads to become able seamen and capable petty officers, and develops midshipmen into captains and admirals is exacting. The naval exercises which gradually convert an aggregation of ships into a fighting fleet instantly responsive to the will of its commander, are arduous and unending.

The peace-time preparation of the fleet is carried on at sea or isolated anchorages, with none of the glamor of battle or the stimulus of war; it would become plain drudgery except for the animating spirit of the Navy that has been handed down from Paul Jones.

Pay the Navy personnel a visit on their annual day at home. Your interest will stimulate their future endeavors, and we believe you will come away a better American and more conscious of your obligations as a good citizen. The Navy selected Theodore Roosevelt's birthday for their annual day at home because that stalwart American devoted himself to increasing the efficiency of the fleet. Whether you are able to visit the Navy or not, remember his famous maxim, "Speak softly, but carry a big stick."

Great Britain Taken to Task by League of Nations THE Mandates Commission of the League of Nations is apparently taking its duties seriously, for it recently criticized the British Government severely for its failure to foresee and prevent the recent conflicts between Jews and Arabs in Palestine. Mr. Henderson, British Foreign Secretary, made a tart rejoinder and asserted that the Mandates Commission itself did not foresee these outbreaks although kept fully informed of

conditions in Palestine. The exchange of notes will probably close the incident, for the League can scarcely be expected to take punitive steps against Great Britain.

Cynics have hitherto regarded "mandates" as a euphemism for "colonies" but the action of the League officials in the Palestine riots opens interesting future possibilities. And if the League dares to rebuke Great Britain, who with some justice prides herself on her ability as a colonial administrator, it will probably not hesitate to intervene in other instances.

The lot of present day Colonial Ministers is not easy, but if, in addition to answering the petitions of backward peoples clamoring for self-determination, they can be summoned to Geneva to give an account of their stewardship, additional troubles are in store for them.

There has been considerable discussion in England concerning the extent of her liability under the Covenant to use her Navy to enforce a decree of the League. Whose Navy *can* the League call upon to enforce a reform of a British mandate?

This incident, almost trivial in itself, illustrates the helplessness of a League of Nations; if the League authorities had the power to enforce their decisions, the world would be in the grip of a despotism just as real as the Roman Empire; without the power to enforce its decrees against a first rate state, the League can never be more than a common international scold.

Pilsudski and Poland PARLIAMENTARY government has received another setback in Europe. This time Poland chose to trust in its famous Marshal who turned back the Bolsheviks before Warsaw in 1920, rather than in a noisy, factious parliament.

There is nothing in the tragic history of a brave but politically unstable people to indicate that a parliamentary system will preserve Poland from internal disorders or external foes. Her first partition was made possible by factional jealousies and a constitution better adapted to protect Poles from their rulers than Poland from three land-hungry Emperors, possessed of well-equipped armies and endowed with power to use them at will. Poles, having to choose between an inefficient government under representative forms, and a Dictatorship which promises a strong but efficient government, have, like Italy, Jugoslavia, and Rumania, chosen the Dictator.

South American Revolutions THE exile of former President Irigoyen from Argentina is the climax and, we hope, the end of a series of revolutionary outbursts in South America.

Almost simultaneously the governments of Peru and Argentina were overthrown by successful revolts; the government of Bolivia had suffered a similar fate a few months earlier. Whatever may be the causes of these outbreaks, it is apparent that many South Americans still prefer to determine their elections with bullets.

We can not be indifferent to the customs of our Spanish-American neighbors. Peru, in particular, has been on peculiarly friendly relations with our country, and her recently deposed President Leguia was proud to proclaim his friendship for the United States. American mediation was instrumental in restoring one of Peru's lost provinces to her and in reducing the friction between Chile and Peru.

An American Naval Mission has been assisting the Peruvian Government to increase the efficiency of her Navy, and American capitalists have invested large sums to develop the mineral wealth of that small but richly endowed state.

As President Leguia became President by a military usurpation and retained power by military coercion, it will be easy for caustic critics to point the moral, but as during his long tenure Leguia gave his country domestic tranquillity and effected a settlement of the long-standing dispute with Chile, we hope his triumphant opponents will allow him an honorable exile and spare their new régime the needless stain of placing Peru's former President before a firing squad. As our State Department was willing to be considered his friend while he was in power, it should not hesitate to go to his assistance in his distress.

Argentina's deposed President, Irigoyen, prided himself on defying the United States, so in a negative way our relations with Argentina should improve by his deposition. Argentina has more trade with Great Britain than with the United States and many of her important industries are owned by English capitalists. There is a British-Argentine trade association actively engaged in fostering trade between the two countries. This association is preparing an exposition of British goods, to be held in Buenos Aires next year, and the British Government has shown its interest in the success of the exposition by agreeing to send the Prince of Wales as its representative.

England buys much of Argentina's meat and wool and sells manufactured goods to that country. One of the reasons urged against a British Empire preferential tariff is the large Argentine trade that would be adversely affected if Argentina were left outside the British tariff wall.

Mexico

AGAINST the revolutions in South America should be placed the orderly opening by President Rubio of the 34th Mexican Congress. He predicted that Mexico had definitely entered upon an era of peaceful reconstruction. Americans, although not so optimistic as President Rubio, will wish their southern neighbor well. No other country has so large an interest in Mexico's stability and prosperity; and our long forbearance should, by now, have convinced Mexico's rulers that we have no sinister designs on her territory and only wish to see her peaceful and prosperous.

Both Cuba and Panama have shown restlessness under their present rulers, and but for their treaty relations with us, would, undoubtedly, have gone the way of Peru and Argentina. The editor of a paper in Panama regrets that their relations with the United States prevent Panamanians from indulging in revolutions, that are open to all other Spanish-American countries; he extols the freedom of action open to a dictator to achieve reforms unhampered by a laggard legislature; and has nothing but pity for an executive who is under the mortifying necessity of soliciting the ballots of his fellow-countrymen. When we feel superior about our electoral customs, we should remember that many other peoples have little faith in ballots.

FOOTBALL

(*Continued from page 372*)

one-sided to give the new plan a fair trial.

As to the first of the foregoing points brought out in favor of the system, the losing team never had the ball in its possession during the last 20 plays. Concerning the second point, there can be no doubt of the value of the plan—the stop-watch is entirely unnecessary, and all that is required of the official timer is that he be able to count up to 40.

From the spectator-interest standpoint, this test game seemed to prove there was *less* interest shown, which, of course, may have been due to the uneven score. However, using the period-by-play system, in place of the interval elapsed, there is more of a tendency on the part of the players to waste time between plays. When this occurs the number of plays per minute is decreased, and spectator interest tends to wane. In the Brown-Boston University game, the number of plays in both the third and fourth quarters was reduced from 40 to 35 because of approaching darkness.

The data for the eight games studied indicates that the average number of plays per quarter consistently increased slightly in each succeeding quarter, which is as might have been anticipated. As soon as the losing side sees the end of the game is coming nearer, they invariably speed up their game; they lose little time in giving signals and in shifting formations. Thus the average number of plays in the first quarter was 40.3, 41.3 for the second, 41.5 for the third, and 42.9 in the last. The actual time the ball was in motion in the first quarter averaged 2 minutes 55 seconds, and 3 minutes 19 seconds in the last.

A complete chart of the 1929 Army-Notre Dame game at the Yankee Stadium in New York City last November appears on page 371. This chart shows in detail the plays made by each team as the game progressed. The legend, giving the symbols used, is located in the upper left hand corner.

In this very interesting and exciting game not a single forward pass was completed. However, Notre Dame intercepted three of the Army's passes, one of which ended in Elder's famous run and touchdown—the kind of a run that sinks and stays in the mind of the average football fan for years.

Applying Coach Glenn Warner's system of scoring—which awards a point for every first down made and eliminates the try-for-point after a touchdown—the score in this game would have been 12 to 5 in favor of Notre Dame. The Southbenders made six first downs and the West Pointers five. The difference in scores under the Warner method would have been seven, which was the same margin by which Notre Dame won using the orthodox method of scoring.

The two vertical black bars at the right-hand side of the chart represent the time the ball was actually in motion, and the time elapsed from the initial kick-off to the end of the game. The bars emphasize graphically the large difference between the playing time and the elapsed time; it will be observed that the latter is about 10 times the former, which visually explains the statement that you pay about twenty-five dollars per hour to watch football.

Critical travelers *like the* STATLERS

BETTER MAILING CONTAINER SOUGHT

SAFER and lighter packing for parcel-post shipments in the international mails would help to increase American export trade in liquid preparations, according to a statement just made public by the Department of Commerce, prepared by Thomas E. Lyon, Assistant Chief of the Department's Transportation Division.

A method of packaging by a manufacturer of pharmaceutical goods is described in the statement, which follows in full text:

During the year 1929 the United States exported medicinal and pharmaceutical preparations to the total value of 21,282,000 dollars. More than one-half of this sum, or 11,655,000 dollars, composed medicinal preparations for internal use, which usually are shipped in bottles and distributed in small units. This last figure could be considerably augmented by other liquid preparations, such as hair tonics, toilet preparations, and so forth, which are usually sold in similar packages. While a considerable part of this trade is shipped by freight, American exporters have felt that it could be increased if parcel-post shipping conditions were improved. Heretofore it has been necessary in making parcel-post shipments to fill packages with sufficient absorbent material to take up any leakage caused by breakage; the absorbent material, as a rule, exceeded the actual weight of the commodity shipped, and thereby increased parcel-post charges.

A well known manufacturer of pharmaceutical goods recently carried on a considerable series of experiments with a view to improving his parcel-post package and has succeeded in developing an economical package which meets the requirements of the Post Office Department. He has furnished the Bureau of Foreign and Domestic Commerce with a description of this package, as follows:

At first a number of experiments were made with various forms of absorbent material packed around the bottles, the outer container being either waterproof or lined with a waterproof material. None of these produced a satisfactory package, however, and finally this idea was discarded and the work directed toward finding some sort of container or case which would adequately protect each bottle.

Obviously a case was required which would be light, very strong, waterproof, and not too expensive, and inside of this case must be placed a sufficient amount of some absorbent material to take care of the loss of the entire contents of the bottle, if necessary.

The form of protection finally adopted for each bottle was a five-ply fiber-board round mailing case, paraffin-sprayed both inside and out, and with a metal screw cap. The fiber-board of which it is made tests 295 pounds on a standard Mullen tester.

A feature of this case is the fact that the threads which engage the screw cap when the case is closed are formed in the fiber board itself during the process of manufacture, instead of being made of metal and fastened to the top of the tube. Such a method of construction insures an extremely tight closure when the cap is screwed down, for then the top of the fiber tube is pressed very closely against the inside of the metal cap, and, being of softer material than the cap, gives just enough to produce the same effect as if a washer were used. This case was found to be absolutely water-tight under tests conducted over a considerable period of time and with the package in various positions.

The absorbent materials ordinarily used, such as bran, sawdust, and so forth, were all unsatisfactory, and the material finally adopted was crêpe wadding. In using this material it was found that no corrugated liners, pads, or disks were necessary.

In assembling the packages for shipment, sheets of crêpe wadding were first procured of such a size that they were about six inches longer than the bottles, and wide enough to produce an overlap of at least two inches and cause the bottles to fit snugly in the cases. Each bottle was then placed in the middle of a sheet, the material was rolled around it, the two ends were tucked in, the wrapped package slid into the case, and the metal top screwed down tightly. The 12 individual cases were then placed in the corrugated box, and the box sealed with sealing glue under pressure in the customary manner.

The complete box, holding one dozen eight-ounce bottles, weighed 17 pounds 15 ounces. The standard export case, containing six dozen of these same bottles, weighs 120 pounds, or 20 pounds per dozen. In spite of the additional protection given the individual bottles by this method of packing, the total weight per dozen has been reduced over 10 percent.

"U. S." ENDORSEMENT IS FALSELY CLAIMED

FALSELY asserting that their respective products had received endorsement of the United States Government, a beverage manufacturer and a correspondence school signed stipulations with the Federal Trade Commission agreeing to cease the practice. The beverage company also misrepresented the qualities of its product.

Details of stipulations are as follows:

(1.) Statements which do not truthfully describe the properties and powers or the curative and therapeutic effects to be derived from use of a certain beverage will no longer be inserted in the advertisements of a corporation manufacturing such beverages.

The company will also cease representations which imply that the beverage has been approved by the United States Government, and will discontinue assertions to the effect that the preparation is used in government and other hospitals and in sanitariums and is prescribed by physicians and dieticians, unless and until such averments are substantiated by fact.

(2.) Representations tending to confuse the public into the belief that its home study courses of instruction in aviation have the approval of, or are rated, inspected, or graded by the United States Government or have the official endorsement of authorities in aviation, when such is not the fact, will be discontinued by a corporation conducting a correspondence school.

GOLF TAX NOT APPLICABLE TO MINIATURE COURSES

SO-CALLED "miniature golf" has no intrinsic relationship, though there are points of similarity, to the recognized game of golf, according to a ruling of the Supreme Court of the District of Columbia.

A license for the operation of the miniature game, therefore, Chief Justice Wheat of the court ruled, may not be exacted under the provision of the District of Columbia licensing act providing for the payment of a license fee of $5 a day for a golf course or kindred game.

The court directed the issuance of a mandamus against Wade H. Coombs, superintendent of licenses, requiring him to grant a license to the operator of a "miniature golf course" under another provision of the licensing act providing for the fee of $100 annually.

The name, Chief Justice Wheat stated, had nothing to do with making the game kindred to golf, pointing out that sometimes a game of dice is known as "African golf."

TRADEMARKS IN FOREIGN LANDS

THE influence of the common-law theory of property rights in trademarks, writes James L. Brown, Chief of the Patent and Trademark Section, Division of Commercial Laws, Department of Commerce, in a recent issue of the *United States Daily*, is noticeable to some extent in many countries where the common law does not generally prevail.

A recent case in one of the Slavonic countries called to mind the recognition given to certain industrial property rights regarded as inherent by the common law and not so recognized in countries where the civil law forms the basis for jurisprudence. A similar instance in Panama brought to light the fact that the theory of exclusive property right in the first user of a trademark limited to an extent the generally understood meaning of the term "first user." With the expansion of international trade, many of the countries not having the common law system of jurisprudence have given recognition to the intangible property right in trademarks by virtue of prior use.

The American exporter is often confused, if not misled, by the expression of the term "prior user" when considering the rights in trademarks, labels, or other means by which he identifies his products shipped abroad. Considering this expression from a general viewpoint, it would seem that he who first adopts and uses a mark in connection with his goods would generally be considered as a prior user and within the expression of the laws of most foreign countries that a prior user is entitled to the registration and exclusive use of a trademark.

It must be understood that provisions in foreign trademark laws protecting the rights of a prior user are intended to cover only prior use within that particular country and, although one has adopted and is the prior user of a trademark in his home country, the property right acquired thereby is not extensive to other countries where the rule of prior user prevails. It is often because of this misunderstanding regarding such provisions in foreign laws that foreign dealers are able to acquire the right to register a trademark and thereby its exclusive use.

In this connection, however, the laws are not uniform and the right acquired by prior user in many of these countries is recognized only for a limited period of time; that is, the prior user may have a registration by another or subsequent user set aside within a given period of time after the registration has been effected. This period of time in which to oppose a registration by a subsequent user varies from 30 days to three years.

While the American exporter should give particular attention to the protection of his marks in the countries where the first applicant of a trademark is entitled to its exclusive use, he should not be unmindful of the necessity of giving earnest consideration to the question of the protection of his mark in the countries where the prior user will prevail. In practically all countries of that group in which the prior user of a mark is entitled to the registration and the exclusive use thereof, it is also advisable to obtain registration since this is prima facie evidence of ownership and may be required in any action for infringement that may be brought later.

Despite the attention that has been given by the American exporter to the intangible right in industrial property in foreign countries, whether it be in the nature of obtaining patents for inventions and useful discoveries; copyright and literary and artistic works; or registration of trademarks, trade names, labels, and containers; there is a steady increase in the tendency abroad to profit by the good will established through advertising and other media by simulating American products and their means of identification.

PUBLICATION TITLES DENIED REGISTRATION

FIRST Assistant Commissioner Kinnan has held that the Fawcett Publications, Inc., of Robbinsdale, Minnesota, is not entitled to register either the words *Modern Mechanics* or the words *Modern Mechanics and Inventions* as trademarks for magazines in view of the prior use by Popular Mechanics Company, of Chicago, Illinois, of the term *Popular Mechanics* as a trademark for a magazine.

The ground of the decision is that the goods are the same and the marks as applied thereto are confusingly similar.

In the decision, after stating that the opposer had used its mark for over a quarter of a century prior to the adoption of the mark by the applicant, had established a large circulation and spent considerable sums of money in advertising, and that if there is a doubt it must be resolved against the newcomer, the First Assistant Commissioner said:

"It is believed this case is controlled by the decision in the case of New Metropolitan Fiction, Inc. v. Dell Pub. Co. 364 O. G. 778, 57 App. D. C. 244. In this case application was made for the registration of the words *Modern Marriage* as a title for a monthly magazine. The opposer proved priority of adoption and use of its registered marks *Marriage* and *Marriage Stories*, (quoting from the decision). The court further referred to the holdings in the cases of Vogue Co. v. Brentano's, 261 Fed. 420, in which the trademark *Vogue* as the name of a magazine was held to be infringed by the use of *La Vogue Parisienne* as the name of another publication, and Art Metal Const. Co. v. Textile Pub. Co., 54 App. D. C. 75, in which the name *The Office Economist* was held confusingly similar to the name *Dry Goods Economist* when used upon similar publications.

"It is clear enough, and the testimony supports the conclusion, that confusion will result from the use of these two names upon the respective magazines."

INVENTOR NEED NOT UNDERSTAND REACTION

IN a recent appeal from the decision of the examiner finally rejecting claims 1 to 5, inclusive, and claims 8, 9, and 10 on a patent recently issued, Shannon Smith, patentee, emerged victorious. Claims 1 and 3 are illustrative of the subject-matter on appeal:

1. A composition of matter for cutting back bituminous material of the character described, said composition including a mixture of quicklime and Glauber's salt in the proportions of substantially nine parts of quicklime to one part of Glauber's salt.

3. A composition of matter for cutting back bituminous material of the character described, said composition comprising light oil and a mixture of quicklime and Glauber's salt in the proportions of substantially nine parts of quicklime to one part of Glauber's salt.

The references relied upon by the examiner are:

Amies (Br), 9929, of 1909; Erwin, 1409088, Mar. 7, 1922; Amies, 951471, Mar. 8, 1910.

Each of the appealed claims is comparatively specific, drawn to a composition of matter for cutting back bituminous material and including a mixture of quicklime and Glauber's salt. Some of the claims include additionally specific proportions of these ingredients and a light oil.

This specific composition of matter for the stated purpose is not disclosed in either of the cited patents. The nearest approach to a disclosure of such composition is found in the Erwin patent, but this patent is indefinite as to the character of the lime employed and fails to disclose the use of Glauber's salt.

The contention of the examiner to the effect that sodium sulfate, broadly considered, referred to in the references, is the same as Glauber's salt, has no basis in fact, Glauber's salt being a specific form of sodium sulfate.

As the applicant's composition is specifically new and as it possesses advantages in the particular use to which it is employed over the compositions disclosed by the references, no reason is apparent why the appealed claim should not be allowed.

With reference to the examiner's contention in his supplemental statement to the effect that the explanation contained in the affidavit of James F. Carle that there is a reaction between the quicklime and Glauber's salt, wherein the quicklime takes up the water of crystalization of the said salt, thereby absorbing a portion of the heat evolved by the slaking of the quicklime to such a degree that the light oils of the bituminous materials are not evaporated, is inconsistent with the specification and claims, which make no mention of such a reaction, it may be stated that such contention is without basis in fact. The claims on appeal are wholly consistent with the original disclosures and the original claims. They are perfectly definite as to the character of the composition and its use upon the bituminous material. They are addressed to one skilled in the art and to practice the invention it is only necessary to employ the described composition in the described manner. An inventor is not required to understand the chemical reactions which take place in a composition, a disclosure of the composition and how it is employed constituting a full compliance with the law (section 4888 R. S.).

The decision of the examiner is reversed.

PAPER TRADE MEN QUIT UNFAIR COMPETITIVE METHODS

WITHDRAWALS of unfair competitive practices in the paper trade are reported by the Federal Trade Commission in two stipulation proceedings, one with a publisher of a monthly magazine devoted to the interests of the paper and pulp trade, the other with a company dealing in paper products.

Details of these particular cases are as follows:

(1.) The publisher of a monthly periodical devoted to the interests of the paper and pulp trade will no longer republish or reproduce printed material published by his competitors when such purported reproduction is not complete, unless he prints along with such information notice to the effect that it is not complete.

(2.) Use of the word "mills" in advertising will be discontinued by a corporation selling and distributing paper products so as not to deceive buyers into the belief that the company owns or operates a mill in which the products sold by it are made, according to a stipulation agreement between the company and the Federal Trade Commission.

BOOKS SELECTED BY THE EDITORS

THE PERSON OF EVOLUTION—*By W. D. Lightall, LL.D.*

THIS is not a book on evolution as the word generally is used, but on philosophy. Science does not attempt to go behind appearances, while philosophy does. Within the past five years a growing group of the world's ablest, most profound men of science—Compton, Millikan, Russell, Wheeler, Whitehead, Eddington, Smuts, Haldane, Needham, and others in high circles—have invaded the domain of philosophy and, though they differ somewhat in their interpretation, their thought centers around what might be called a scientific "religion" of "emergent evolution." Of this new trend, which rationalizes the more common emotional, revealed type of religion, the book under review is a splendid summary of 216 pages.

The central idea is, that the whole Universe, whether "inert" or living, is evolving toward a definite goal, imbued with a reasoning, directive, purposive power or "Outer Consciousness," the "Person of Evolution." Of this superpersonality or composite reasoning being, all lesser individuals, including ourselves, are extensions. This in turn explains our inherited memories, instinctive fears, the so-called instincts of animals; our conscience and altruism; and immortality.

This whole new trend toward a spiritual interpretation of the world is opposed to the materialistic interpretation by which all events are simply the mathematical resultants of causes, without intervention of purpose; likewise it favors the vitalistic concepts of life which, however, seem to most men of science to border on mysticism. The author concludes that "religion and science are not in two compartments, as nearly all the leading theologians and nearly all the leading present men of science say they are." —$2.20 postpaid—*A. G. I.*

WE have been asked a number of times what the italicized initials mean that appear at the end of some of the book reviews. These are the initials of the reviewing editor.

***A. G. I.*—Albert G. Ingalls, Science**

***A. A. H.*—Albert A. Hopkins, Fine Arts**

***F. D. McH.*—Fred D. McHugh, Engineering**

***A. P. P.*—A. P. Peck, Radio, Television**

Where no initials appear the review is by L. S. Treadwell who has responsibility for this department and to whom should be directed any questions that you may care to ask concerning books or other subjects upon which you desire information: Our staff cannot always answer your queries (no small collection of men can possibly envision all knowledge) but it is seldom that we are unable to give some tangible reference.

WAVE MECHANICS—*By A. Sommerfeld, Prof. Physics, Munich*

THE rapid succession of published papers on the theory of the atom and on atomic phenomena generally makes it almost impossible for the ordinary physicist to realise the present position of his subject. Professor Sommerfeld has brilliantly performed the task of surveying all the recent important developments and has also treated a number of the older facts in a new way. The achievements of de Broglie, Heisenberg, Schrödinger and Dirac are clearly set out, and it is shown how the weaknesses inherent in the Bohr atom have in many cases been successfully overcome. The work is almost wholly written in higher mathematics.—$6.40 postpaid—*A. G. I.*

INDUSTRIAL REFRIGERATION, COLD STORAGE AND ICE-MAKING—*By A. J. Wallis-Tayler*

THIS seventh edition of an English work covers the entire subject most thoroughly in 162 pages, with a final chapter on small commercial and household refrigerating plants. It is a history of refrigeration as well as a text book of current practice and is a reference of international comprehensiveness.—$10.25 postpaid.

INDUCTION COILS—*By F. E. Austin*

THERE has been real need for a work on this subject because of its application to automobiles, telephony, wireless telegraphy, and X-ray diagnosis. This little volume so trenchantly and completely presented will be welcomed by those who have been unable to uncover this information in other sources. Specific instructions for building large and small coils to operate wireless outfits are also included. A most complete and satisfactory presentation.—$1.15 postpaid.

ABC OF GLIDING AND SAILFLYING—*By Victor W. Pagé*

GERMAN experience extending over a number of years has been largely drawn upon to furnish the material for this simple and practical treatise, prepared with special reference to the needs of young beginners in aviation. It gives diagrams of many of the important planes with details of materials used and the general construction. Formation of gliding clubs and details of training are adequately covered.—$2.15 postpaid.

THE CONQUEST OF LIFE—*By Theodore Koppanyi*

THE subject of this 256-page book is biology—anatomy, embryology, evolution, heredity, physiology—but it is not at all like a textbook, rather is it designed for pleasant, though serious reading. The author has chosen some of the "pleasant spots" of this big broad science and dwelt on them at considerable length and with more than considerable interest. The chapter on the endocrine glands and the one entitled "Masculine and Feminine" are especially notable.—$2.15 postpaid—*A. G. I.*

THE GREEN LEAF—*By D. T. MacDougal, Carnegie Institution*

THE "major activities of plants in sunlight" (sub-title of the book) have been kept too largely in the dark and many of us therefore think of plants as dull inanimate things. But Dr. MacDougal's new book—which, by the way, concerns mainly what goes on in the insides of plants, an aspect we seldom hear of—shows that they are almost as human and interesting as monkeys. The "visit to the green-leaf mills," in which we actually crawl into a manhole in a 100,000-times magnified leaf and climb around the interior, reveals what a lively chemical laboratory a leaf is. Other inquisitions on trees bring to light whole factories full of hustle and bustle and machinery, of which most of us are not aware, perhaps because, unlike animals, trees do not roar or bark. The author's life work has been devoted to research on these silent manufacturing centers and the book represents information at first hand from a noted man of

FROM RECENT PUBLICATIONS

science. In addition it is full of interest; for example, such things as that a healthy tree manufactures lumber at the rate of one broomstick a day.—$2.15 postpaid.—*A. G. I.*

THE MOUND BUILDERS—*By H. C. Shetrone, Dir. Ohio State Arch. and Hist. Soc.*

FOR a long period of years there has been no up-to-date, all-around treatise on the mound builders, but at last one has been published and it is a rarely good one. Dr. Shetrone, than whom no scientific authority is better fitted to write on this subject, has made a splendid round-up of the whole field. The book has two parts, 165 pages being devoted to the various cultural phases of the mound builders, while in the remainder of the 500 pages the known mounds, of which there are myriads, are taken up systematically region by region, state by state, from Gulf to Canada and Atlantic to the West, and dealt with in detail. Finally, the intriguing question "Who were the mounders?" is discussed scientifically. The style is wholly non-technical and replete with interest, while the handsome, rather large volume (6½ by 9½) is printed in good type on fine, heavy, filled paper, has 299 illustrations, and is attractively bound. This book doubtless will be *the* standard work both for reading and reference during many years to come.—$7.70 postpaid.—*A. G. I.*

THE SECRETARY'S GUIDE—*By C. O. Sylvester Nawson*

NO more useful little book has come to our desk in a long time. It covers thoroughly, in most condensed form, the correct modern usage for spelling, compounding, capitalization, punctuation, abbreviations, figures and numerals, sizes and styles of type, use of italic, spacing, proofreading, correspondence, and diction. It goes at once on our reference shelf and we predict it will be used frequently as its general utility is much greater than the name indicates.—$2.15 postpaid.

THE ENLARGEMENT OF PERSONALITY—*By J. H. Denison*

THIS is not a psychological treatise in the sense we generally understand that term, but a common sense discussion of the facts of consciousness which are a matter of common experience and of historic record and a suggested interpretation of them. If a man is given a new and different idea of what he is, that idea in many instances will so recondition his reactions that his behavior and character will be materially altered. The process and proof are carefully developed by the author.—$3.20 postpaid.

THE REAL WAR 1914 TO 1918—*By Captain B. H. Liddell Hart*

EXPERT diagnosis is usually so detailed and laboriously compiled that one reads with a considerable sense of compulsion. Here the author gives us a quick resume of the official facts and their significance. "The Origins of the War"—Chapter I—is the clearest, most comprehensive review that we recall reading. The stories of the various major engagements run smoothly and vividly. Facts are discussed and sentimental reputations are no bar to criticism and a fearless endeavor properly to evaluate the tactical value of leadership. We believe this work will rank high in the more analytical literature of the late war. 495 pages and a most complete index.—$4.20 postpaid.

NEW WAYS TO MAKE MONEY—*By Roger W. Babson*

"TO help young people in selecting a vocation which has a great future"—to quote the author. Incidentally we might add that the adult might well give it careful reading for the keen insight into industry and business which with swift, decisive, almost curt sentences outlines the various opportunities in a wide variety of lines of effort. There have been other good books on "Choosing a Profession" and so on, but none to our mind quite so inclusive yet almost statistical in its briefness, as is this text.—$2.65 postpaid.

ROUGH AND TUMBLE ON OLD CLIPPER SHIPS—*By Captain Bob Ramsay*

THIS rousing, hearty story by an old shell-back is vivid with life, character study and tales of feats of the fast clipper ship in strange seas and foreign ports. It relates adventures of shark fighting, mutiny, and stern discipline, material ranging from deep sea diving to navigation on the Great Lakes. Primarily, however, the real rough adventure which attended the heyday of navigation is the keynote. A real tale by a real sailor.—$3.20 postpaid.

THE WILD GRIZZLIES OF ALASKA—*By John M. Holzworth*

THREE years collecting material for the U. S. Biological Survey enabled the author to study the grizzly and big brown bear as well as mountain sheep and caribou. An experienced scientific observer with all the enthusiasm of the tenderfoot writes in conversational style of most adventurous experiences, many of which give an entirely different idea of these wild beasts from that generally understood by most of us. 95 beautiful photogravure illustrations.—$5.20 postpaid.

UNVEILED—*By Selma Ekrem*

AN accomplished Turkish girl of distinguished ancestry gives an intimate picture of the daily life of an official family during the period of the struggle for freedom from the tyranny of the times and of war. All the hopelessness of oppression, the hopefulness of brighter days ahead, the swaying back and forth of the fortunes of war and despotism are depicted with an extremely facile pen, to make a story that is truly unique in subject matter and viewpoint.—$3.20 postpaid.

RIDERS OF THE PLAGUES—*By James A. Tobey*

AN accurate description of some of the worst plagues that have afflicted the world and the way man found out about them and conquered. Also an appreciation of many of the valiant men and women who have been responsible for some of the most dramatic events in human history—a story abounding in pathos and heroism. The author is an expert in public health, so he brings to the subject sound knowledge and fervent enthusiasm.—$3.65 postpaid.

WILD FLOWERS—*By James E. Jones*

A UNIQUE and happy arrangement of the familiar wild flowers and weeds grouped alphabetically by color orders. One need know nothing about botany speedily to locate a specimen, when will be found the colloquial name, the botanical name, and a short note covering occurrence and range with often an item of special interest.—$1.65 postpaid.

We Can Furnish the Above, as Well as Any Other Books That Are in Print, at List Prices, Plus Postage

SCIENTIFIC AMERICAN

● Go to High School at Home

You can secure a high school education right at home by studying the splendid new courses recently prepared by the International Correspondence Schools.

These courses are equivalent to the courses given in resident high schools. They have been specially arranged for men and women who wish to meet college entrance examinations, to qualify for a business position, or to make up the education they missed when forced to leave school too soon.

The College Preparatory Course, the High School Commercial Course and the High School English Course include English, algebra, ancient, medieval, modern and U. S. history, physiology, literature, geography, Latin, bookkeeping, drawing, geometry, shorthand, physics, chemistry, salesmanship, advertising, civics, trigonometry, economics, corporation finance, trade economics and other subjects. A diploma is given at graduation.

The lessons are easy to understand and you will make rapid progress because you will be *in a class by yourself* and will study under the guidance of instructors interested in helping you achieve the bigger things of life.

Just mark and mail the coupon and we will gladly send you free booklets describing the I. C. S. High School Courses or any other subject in which you are interested.

INTERNATIONAL CORRESPONDENCE SCHOOLS

TWO SURVIVING PIONEERS

THE first dynamo built in America, like the surviving one of the two Cornell professors who built it in 1875, still is in perfect working order at Ithaca, New York, where it furnishes power to the students' shop in the physical laboratories of that institution. "In 1875" says the physicist Edward L. Nichols in the *Cornell Alumni News,* "Gramme brought out in Paris his form of dynamo machine, and no sooner had the description of it reached this country than Anthony and Moler (Professor W. A. Anthony and Professor G. S. Moler—the latter appears in the picture, which is recent—Ed.) undertook to build one. Long before the first imported dynamo reached America this machine was successfully completed and in operation. With it, before the close of the year, arc lamps were installed on the Cornell campus and were put into regular service, and thus it came about that inhabitants of remote farms among the hills of central New York saw the arc light shine out nights, years before the introduction of this means of illumination in Paris, Berlin, New York, or any of the great cities of the world." Professor Moler told a member of the SCIENTIFIC AMERICAN staff that he and Professor Anthony were forced to wind all the wire with home made insulation. Insulated wire was not available in 1875. The wiring of the outdoor lighting system was underground and the cables were made by drawing copper wire through gas piping and pumping tallow into the pipes, a method which nevertheless proved very satisfactory.

NEW "EARS" FOR FRENCH ANTI-AIRCRAFT GUNNERS

TO keep pace with the great strides made by military aviation since the war—that has been the problem of the anti-aircraft sections of the artillery of all nations. The efforts of the French to do this are symbolized by this new device, by means of which ground crews listen to the approach of an enemy plane, "focus" upon it, and determine its position and altitude. While no details have been released concerning this apparatus, which was tested in recent French aerial maneuvers, it is said to register the sound of planes 20 miles distant. Although aero-detectors have been demonstrated before, this one is interesting because of its novel construction.

Plowing in North China. A man is often a more economical draft animal than a mule

A 4000-YEAR FOOD EXPERIMENT

By **WILLIAM H. ADOLPH, Ph. D.**

Associate Professor of Chemistry, University of Nebraska.
Recently appointed Professor of Chemistry, Yenching University, Peking.

THE average Chinese lives on but a few cents a day. This is not a myth, nor is it a sign of poverty; it is a simple statement of an economic accomplishment of which China may justly feel proud. We in spendthrift America should at least stop and honestly study China's sane solution of her food problem.

The brief experience of the Occident becomes ridiculously insignificant when compared to the 4000 year experiment which the Orient has conducted on the feeding of large numbers of people. In present day laboratory studies the scientist measures the nutritive value of a diet by feeding tests upon a small colony of perhaps ten or a dozen caged animals. The experiment is brought magnificently to a close after 30 or 40 days, during which the white rats for example have grown or failed to grow on the diet in question, and the conclusions are pronounced with due finality; only recently has it been realized that laboratory feeding experiments must often extend over not only several days, but over several generations before satisfactory conclusions can be drawn.

But here in eastern Asia is a colony of 400,000,000 people who in response to various environmental factors, and possibly racial factors, have adjusted and readjusted their food habits until the present *status quo* was reached! And this condition of established food habits would seem to have remained unchanged for the last thousand years or more.

We, with our new civilization, are still undergoing adjustment to new environmental and economic influences and have not yet reached a state of stable equilibrium. In laboratory experiments, a nutritional equilibrium such as the Chinese would seem to have attained is exactly what the biochemist seeks. The thoughtful nutrition chemist loaded with the faddist lore of the Occident can not but sit as a humble observer before this long term experiment and its accumulated mass of evidence. The Chinese would seem to have sensed certain fundamental principles of food supply long before they were discovered by the up-start West.

The Author

CHINA from ancient days has been an agricultural country, and it is still essentially agricultural. Certainly less than 10 percent of the population are found in the large cities and even these are mainly engaged in trade or industry involving agricultural products. The encroachments of the new industrialism may soon begin to alter this state of affairs, but so far there has been little measurable change. The majority of the people eat what they raise. China continues to feed herself largely in terms of a hand-to-mouth operation. The very thoughts of the people, and the language background, are agricultural. A man's wealth in China is expressed not in dollar marks, but in acres of land. An institution in America may possess an endowment of so many million dollars; in China it is endowed with so much land.

The race for the almighty dollar becomes in China the struggle for land, and this in time produces population pressure. The American and European can calculate the amount of money needed to feed and clothe each member of his household per year. The Chinese glibly reckons this factor in terms of land area, or *mow*. In Shantung, it requires three *mow* to support one man; or, poorer land would be rated as four-*mow* land.

This situation means that practically every available plot of land is under cultivation. Farms may be little more than a single furrow or two hanging on the mountain slope. It is significant that

TABLE I

Composition of the Chinese Dietary
(in percentages by weight)

	China North	*United States*
Cereals and beans	65	25
Vegetables and fruits	27	20
Butter; fats; sugar	1	14
Meat and fish	4	18
Eggs	1	5
Milk and cheese	0	15
Other foods	2	3

the size of a family is commonly expressed as consisting of so many "mouths," much as industrial Europe and America refer to so many "hands." The primary aim of each household is to work that bit of land intensively enough to keep the family alive for another half year, or until the next harvest. Ambitions in the big majority of homes do not proceed very far beyond this sphere. This tremendous pressure for a livelihood is not a condition of recent years, but history shows that in very early times there were laws in China regulating the conservation and distribution of food. Our science of national food economics, urged upon us by the World War, is hardly a 20th Century discovery!

A Chinese highway eighteen inches in width effects a saving in land area available for cultivation, which means food for more mouths

TABLE 1 shows the character of the middle class Chinese diet compared with that for the United States. It is a cereal diet. While these figures are for north China, they are in general true for south China also, except that in the northern third of China the cereal is largely wheat, used as wheat bread, while in the southern two thirds of the country the cereal employed is rice. The common assertion that the Chinese live on rice is therefore only two thirds true. The division into north and south China, that is, a wheat-eating region and a rice-eating region, is a well-recognized one. Habits of life, climate, and agricultural conditions in these two areas also differ greatly. North China has a dry climate; south China is wet. Data now being accumulated for south China, while as yet incomplete, indicate that the only real difference between the dietary of the two areas is in the replacing of wheat by rice. The same fundamental laws of food economics hold throughout the country.

The important place occupied by legumes (this means the soy bean) in China deserves more than passing mention. Of all the varieties of beans, it is nothing short of remarkable that the Chinese farmer-dietitian, thousands of years ago, chose to develop and retain in his agricultural repertoire just that one variety which contained the highest percentage of protein, and also the highest percentage of fat. The soy bean was the one vegetable product which could in any sense replace meat in his dietary. But the soy bean and its wonders is another story.

It is evident that China is not addicted to the meat eating evil. Table 2 shows that the daily food intake represents a total of about 2800 calories. But of this amount, 87 percent is derived from cereals and beans, while only five percent of the calories is supplied by meat and fish. And these data do not represent the farmer class, but are those of the middle class Chinese. Meat is relatively more expensive in China than in America and Europe. The peasant farmer consumes practically no meat at all, except for an occasional indulgence at the time of the Lunar New Year. It is probable that the Chinese approach as near to being a truly vegetarian people as is to be found anywhere on the earth's surface.

Figure 1 is a "dollar diagram" indicating the manner in which the average Chinese family divides its expenditure for food. The Chinese housewife very evidently spends her food dollar in a different manner than do we. It is to be noted that eggs are used only in small quantities; milk and dairy products are conspicuous by their absence.

Meat and cereals are important because of their protein content. Protein of course is the all-important nutritive factor of all foods. The nutrition chemist of a generation ago devoted his energies to determining the total number of grams of protein consumed by the individual per day. It was not then known that the kind of protein was as important as its quantity. We now know that the amount of protein is only part of the story. One hundred grams per day (about 35 ounces) is regarded as the protein requirement for the average adult in the Occident, weighing 70 kilograms (154 pounds). In America we actually consume far more than this amount; the Chinese consumes somewhat less. But when, in addition to this, it is remembered that a vegetarian diet is a much bulkier diet than the meat-containing diet of the Occident, and that the degree to which this protein is utilized in the alimentary canal may be reduced by the very bulk of the food to 50 or 60 percent of its original value, one realizes that the Chinese receives in reality an extremely small amount of protein nutrient daily. In fact, the actual intake for a man of 60 kilogram weight on rice diets may be only 35 or 40 grams (about 14 ounces) per day. This low protein diet again represents a habit of long standing. Have the Chinese indeed accommodated themselves to a lowered protein intake? And if it should be proved that they have done so successfully, perchance the figure for protein requirement which we have established will need revision.

DIETARY surveys show that 91 percent of the protein consumed is of vegetable origin, while nine percent proves to be of animal origin. In America about 80 percent of the protein consumed per day is from animal sources. Much has been written on the relative merit of animal and vegetable protein, of the meat *versus* the vegetarian diet. It is commonly suggested that the aggressive peoples of the world consume large quantities of meat. Table 3, taken from Robertson's "Principles of Bio-chemistry," expresses quantitatively the meat eating habits of the nations. The figure for China has been added to this table by the author and is based on

TABLE II

Composition of the Chinese Dietary

Intake of protein, total energy value, and so on, per man per day (Figures are for North China).

Total food	1188.0 grams
Total protein	86.4 "
Total fat	34.1 "
Total carbohydrate	537.0 "
Total energy value	2794.0 calories
Weight of average man	60.0 kilos

observations in Chinese homes and on such trade reports as were available. One wonders whether it is possible to explain certain of the racial characteristics of the Chinese in terms of this low per capita consumption of meat.

That a vegetarian diet rather than a meat diet holds sway in China can be traced to economic factors. The food-consuming animal is a mechanism which transforms food energy into heat or work or even into other forms of food, as into meat for example, which can again be used as food; the animal body, in short, is a converter. Studies in this country during recent years have shown the relationship pictured in Figure 2, which indicates that the transformation by cattle of food cereal into milk or into meat is always attended by considerable loss, a "transformer loss." China in her unconscious way has realized this. At least she has realized that the cereal grains are most economically employed directly as human food.

AND yet this knowledge is not solely unconscious knowledge, for the peasant farmer will tell you that he can obtain a greater return per acre by growing peanuts and extracting the peanut oil than by pasturing a cow in this same field and manufacturing butter or cream—which is merely another variety of oil—from the milk. In fact he knows this so well that for the past thousand years or so he has not even regarded it as worth while to perform the experiment. Just here, incidentally, lies the economic stimulus for our own vegetable oil industry. And we of the West have just come to the stage of measuring these things and have discovered that they are quantitatively true. Do we wonder that China eats little meat and that there is practically no dairy industry!

And the Chinese use of pork is equally startling. Only recently has it been demonstrated by modern science that an acre of ground in the form of pasturage produces two pounds of pork for every pound of beef or mutton. So when meat is used in China, it is pork. The laws of economics have dictated far more of the actions of the Oriental than we realize. A man instead of a horse pulls a ricksha because a man is a machine weighing only 60 kilograms and its cost of maintenance is less than that of a horse which is, say, a 600 kilogram machine.

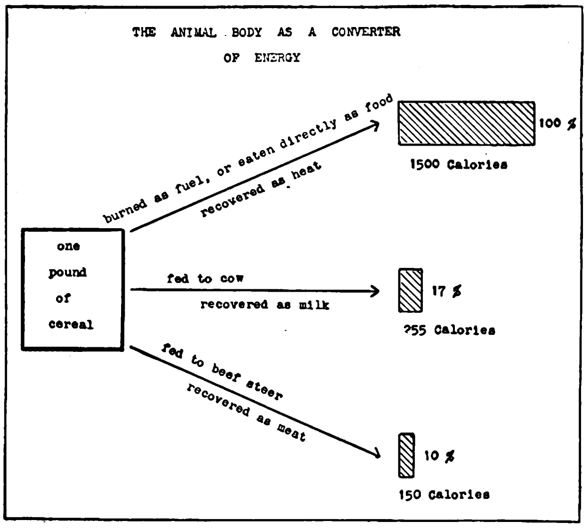

Figure 2

In times of special stress affecting the food supply, such as may be brought about by famine, the farmer tends to dispose first of his draft animal, a luxury. Even when there is no famine at all, it often becomes more economical to hitch a man to a plow than to use a mule. The one-wheeled cart, which requires only a narrow, 18-inch-wide path for its operation and thereby saves more tillable land to the fields on each side of the road, is but another instance of the manner in which economic laws hold the commanding position.

Blind experiment, that guiding angel of the Orient, was kind. It taught the Chinese the importance of vitamins, or at least the importance of vitamin-containing foods. Today, recognizing the importance of vitamins and similar food essentials, we wonder that China not only survived but flourished on a straitened food supply. But China has long been making use of green vegetables, spinach, cabbage, and so on, and fruit. And we of the Occident, having just discovered vitamins, are now busy haranguing our housewives and urging greens in the diet—and often with ill success. Wheat protein and rice protein are now known to be incomplete proteins, but recent American patents suggest that wheat protein should be supplemented with soy bean flour. Effective combinations like this were in fact *discovered* by the allied food experts during the World War and were served to the soldiers at the front in the form of "war bread." China, on the other hand, has for centuries been making use of similar combinations of protein food materials. In addition to this, infants deprived of the nourishing protein of cow's milk are insured the growth-promoting essentials by being breast-fed till three or four years old.

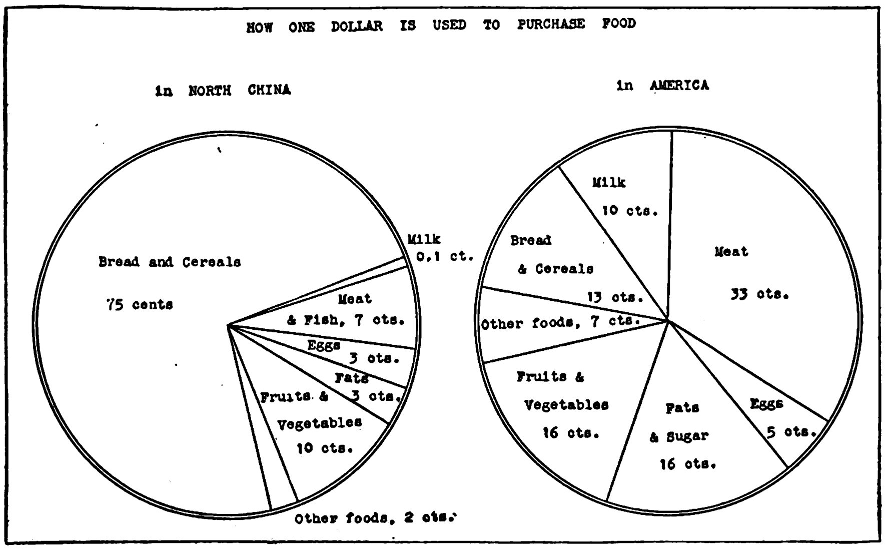

Figure 1

THE great bulk of the Chinese vegetarian diet is often looked upon by us with suspicion. It is such a considerable factor that the Chinese student coming to America finds it difficult to adjust to the smaller bulk of our more concentrated mixed dietary. He asserts that a period of a month or more is required till the digestive system accommodates itself to our small bulk meal. During this period of accommodation of course he finishes each meal with appetite still unsatisfied, and goes hypothetically hungry. We of the West formerly asserted that our type of diet was more concentrated and hence more efficient. But our own dietitians now urge roughage—and more roughage. The Chinese diet however, means a freedom from the multitudinous intestinal disturbances which affect the Occident. Laxative pills are not every-day essentials, and druggists in China must look elsewhere for means of livelihood.

Does the Chinese metabolize on a more efficient plane? Much interest has developed during the past few years in the basal metabolism of the peoples of eastern Asia. A few years ago an experiment at Teachers College, New York, upon a few Chinese women students indicated a much lower basal metabolic rate than would have been expected in the case of American women

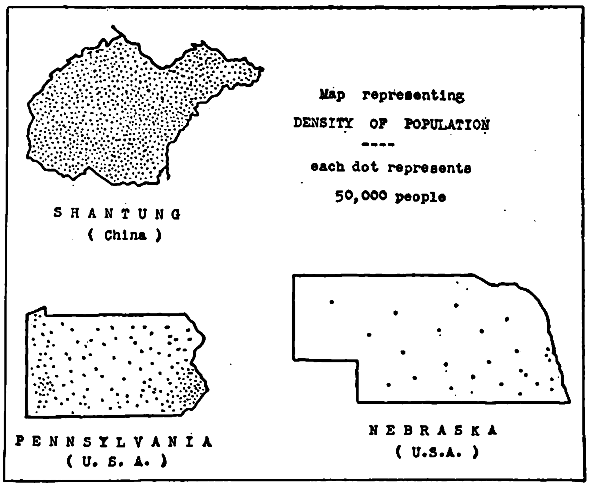

Figure 3

students. The basal metabolic rate, about which our physicians are beginning to talk in such familiar terms, is nothing but a measure of the energy required just to keep the human engine alive at rest without doing work except that involved in breathing and the other essential functions. Does this lower figure mean, the physiologists all asked themselves, that the Chinese human mechanism is a more efficient machine than that of the European and American? Does it mean, asked the nutrition chemist, that the Chinese people need less food to keep them alive than their American neighbors of equivalent weight?

More exhaustive data is now being obtained; portable metabolism outfits have been sent by the Carnegie Nutrition Laboratory of Boston to different parts of the world to settle this point as it applies to the different races. It may be suggested that the lower figure for basal metabolism is the normal for the human race, and that the rush of the Western civilization has merely produced a higher metabolic rate in the Occident, while the philosophic Orient has avoided this abnormal high tension effect. Or the low metabolic rate for China, if confirmed, may merely indicate that the Chinese can truly live longer on a lower ration than is required by the European.

TABLE III

Meat Consumption of the Principal Countries of the World

(grams per capita per day)

United States	149
Great Britain	130
France	92
Belgium and Holland	86
Austria-Hungary	79
Spain	61
Russia	59
Italy	29
Japan	25
China (North)	15

Are metabolic traits inherited or environmental? The dietary and metabolic habits of a race presumably either are inherited or are the result of the reactions of environment. The very fact that Chinese leaving China and Occidentals domiciling in China find that certain physiological reactions are temporarily altered would point strongly to environment as the influential factor. North China and south China each represent different types of climate and diet, and when the southern Chinese migrates to north China and adopts north China food, his sons begin to approach in height and weight the higher standards of the northern part of the country.

Environmental factors often do not reveal themselves in a single generation. The Japanese who settled in the United States a generation ago are now developing a larger physique approaching western standards. Cantonese from south China who emigrated to Hawaii are now, after several generations, attaining greater physical height than they did in south China. The blood pressure of Americans moving to China approaches the lower Chinese standard, while Chinese coming to America tend to approach the higher American norm, while the basal metabolism itself of the Westerner moving to south China is apparently lower than it would be at home.

MANY different races now compose the white population of the United States, yet we generally agree that the same physiological standards hold for all of them; at least there have not been discovered among them distinct racial reactions of a purely physiological character. The so-called racial characteristic as distinguished from the environmental factor would therefore seem ultimately to disappear in the realm of food and metabolism.

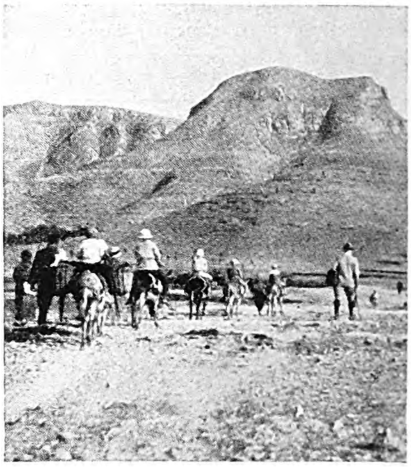
While it may be a distinct accomplishment to have been able over long periods to feed a nation on a minimum food intake, this habit of merely maintaining an existence has provided no insurance against interruptions in the regular food supply. The tables and figures reproduced in these pages indicate that the Chinese people live constantly on the fringe of starvation. There is absolutely no margin or reserve. A famine in China is primarily a violent disturbance of the delicately balanced economic *status quo*—so violent that the common people find it difficult or impossible to buy food. Drought, floods, grasshopper pests, revolution, are disturbing agents. And they are usually augmented by ill-developed means of communication, such that the areas with excess food supplies can not automatically unload their surplus unconsciously, as is done in America, on the regions where the demand is high and the supply low. One crop failure in a district brings about enormous suffering; two crop failures result in famine and starvation; and three successive crop failures in the same district produce havoc and devastation.

MOREOVER, human beings in China do not always die of starvation to the extent that they die from disease caused by a weakened physical condition. Food intake and health are closely related and famine studies show how a very slight lowering of the quality and quantity of food intake produces immediate disaster.

China, while receiving credit for a finely balanced solution of her food supply problem, is at the same time face to face with the fact that the prosperity of the nation demands not mere maintenance, but an optimum metabolism expressed in terms of improved growth and vigor. It is hardly to be doubted that in this modern age, with its new demands, China will rise to a solution of these newer problems with all the thorough-going capacity which she has displayed in the past.

●

¶ *When Professor Goddard's exploring rocket soars 50 or 60 miles aloft what scientific instruments will it carry? What will be their purpose and what the practical value of their findings? Next month this will be explained clearly and simply.*—The Editor.



One effect of population pressure: a deforested mountain in North China. Population pressure results in the unconscious discovery of some valuable methods, such as hogs as the most efficient source of meat, but the deforestation that also occurs is not one of these

OUR POINT OF VIEW

SPEND FOR PROSPERITY

UNTIL a few months ago, there was, among industrial and business men and all people of the thinking class, a feeling of optimism regarding the economic depression, an optimism not of the Pollyanna sort but rather of a constructive nature. Many splendid plans were advanced as possible means of stimulating business recovery but nothing much has been done toward adopting any of them. And now, even the thinking optimists, as well as the Pollyannas, have turned lugubrious pessimists.

What is the matter with the American people?—that "race" which is famed for and vaunts its ingenuity, industriousness, and ability to the world. They are not unaccustomed to slumps; they've had them before. Where is that comeback, that fight, that will-to-win, bear-for-punishment spirit? Are they, to whom the world looks for a certain amount of guidance and, unfortunately, with envy and hate sometimes, because they *have* possessed a progressive spirit and an acquisitive instinct—are they to be cowed, to admit defeat and wait for someone else to start the world back toward normal conditions? Usually only the mongrel dog slinks away, whining, with his tail between his legs.

The country is not in such a bad state, after all. September disbursements of dividends to shareholders were nearly 76 millions of dollars more than for September, 1929. There was a large increase in the number of dividends omitted and reduced, but the total disbursements were 475,094,394 dollars compared with 399,391,264 dollars in September, 1929. This can mean only one thing: that while many businesses have suffered losses, many others profited far more than they did before the slump. There may be drawn from this the conclusion that if some can prosper, others can at least make a new start and grow. But somehow it hasn't seemed to work that way.

Long-established and vital industries that have withstood for months the laments of the pessimists, have at last succumbed and inaugurated programs for retrenchment that are sure to have a devastating effect, not only because they will withdraw many millions from circulation but also because they will further lower the morale of all those who hear of them. And the distressing part of it all is that our greatest customers, the American workingman and the small-salaried office man, are always the first to feel each new blow. They are discharged in hordes without the slightest prospect of obtaining other employment. Their purchasing power is lowered, business suffers further, and old man "vicious circle" is at work again! And even the man with a job becomes frightened at the possibility of losing his source of income and hoards his money "against a rainy day"—more money out of circulation!

DANIEL GUGGENHEIM

IT is our sad duty to record the death of Mr. Daniel Guggenheim, capitalist, philanthropist, and patron of aviation, on September 28 at the age of 74. Known chiefly to the country at large as the donor of the Daniel Guggenheim Fund for the Promotion of Aeronautics and vaguely as a "copper king"—vaguely, because while his power was tremendous, it was quiet—his interests spread over the world like a far-flung empire.

Mr. Guggenheim's business ability and progressiveness brought continual success to his endeavors but as his power grew, so apparently did his humanity also grow. Identified with the early romance of American mining, expanding his interests to other fields, and ever persistent in his encouragement of scientific research in industry, he yet had time for art and music and flowers. He gave liberally yet quietly, dealt fairly with all, and was imbued with a public spirit that few could equal.

In the death of this valued citizen his friends have suffered an incalculable loss. But his greatness transcends the limits of ordinary personal friendship; in him was the warmth of a great soul, a warmth that radiated outward through contact with him and his philanthropies to touch thousands whose lives, expanded and made finer because of him, shall be his greatest memorial.

In a case such as this it is easier to diagnose than to prescribe. One thing is certain, however, and that is that the American people, collectively and individually, must start a veritable orgy of spending. They must stop hoarding for a while, stop being frightened, stop crying "hard times" and put money into circulation, thus creating a great demand for all sorts of things the manufacture of which will make the wheels hum again and bring a return of prosperity. Time enough, after that is accomplished, to save!

Along with others, we have given up hope for any real help from business itself, and now appeal to the individual. And if that individual is one of those who persistently passes the buck to the other fellow, who is always perfectly willing to "let George do it," we venture to say that if he doesn't cooperate this time, the other fellow, George, may get his job!

INTERNATIONAL AFFAIRS

The Deplorable Cut In Naval Personnel

WE are convinced that the recent announcement by the Navy Department of a contemplated reduction of 4800 enlisted men in the Navy will be a distinct disappointment to the American people, a large majority of whom are willing to be taxed for the support of the Navy. The unplausible attempt to connect this reduction with the provisions of the London Conference will not impose upon the general public, who were only recently told by the Administration itself that a large new building program would be necessary to bring our fleet up to the allowed treaty strength. Obviously, ships without men are useless, so the proposed cut means either that the Administration has no intention of building a treaty fleet or that it does not propose to man it after construction.

The accompanying statement that our fleet is to become a "training nucleus" will still further alarm our people who have been taught to believe that a large standing army is unnecessary because our fleet would be maintained as a sure and ready shield, behind which our skeletonized peace army could expand to war proportions. Now we are to have a skeletonized navy as well as a skeletonized army. The term "training nucleus" has a comely sound, but the American people have too long regarded their fleet as their first line of defense to be charmed by any new catchword, however beguiling.

We also fail to see the consistency of the Administration discharging 4800 sailormen in the present condition of unemployment, while at the same time it requests private employers to refrain

(*Please turn to page 486*)

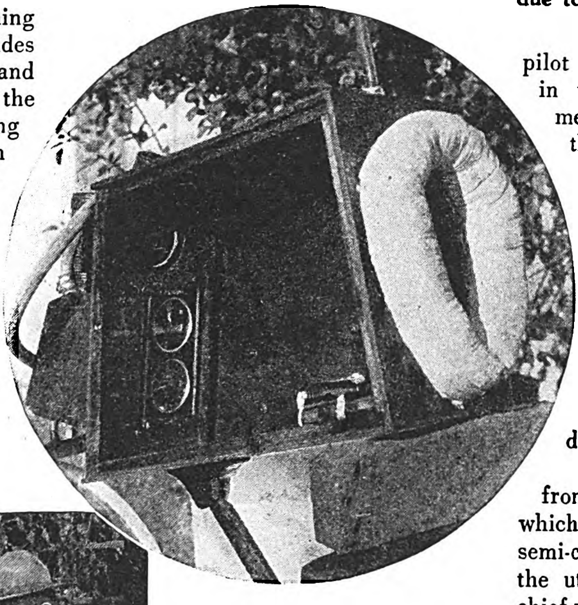
Captain Ocker and Major Mileau, flight surgeon, giving a test with the Barany chair. After a few turns in the chair with his eyes closed, the subject almost falls out of the chair due to effects of vertigo or dizziness

not due to any asymmetries in the legs or other parts of the locomotor organs of the body generally, such as right-handedness.

“One and the same person may walk or swim or drive both right spiral turns and left spiral turns in different experiments or sometimes in the same experiment. No apparent difference is observed in the direction of turning that is referable to difference in age, sex or right- or left-handedness. Spiraling is not a conscious phenomenon. Consciousness gets no direct repeat from the spiraling mechanism. A blindfolded person is conscious of swimming or driving a straight path when he is actually going in spirals. The spirals are smaller, however, when the attention is not intensely directed on the manner of making each step, but is occupied with counting the steps or thinking about something else than walking a perfectly straight path.

“Persons who lose their way in forests, snowstorms, and fogs go around in circles because, in these persons, the orientating senses are not functioning and then the spiral mechanism guides the path. Rabbits, foxes, antelopes, and other game, when hard-pressed in the chase, lose the power of orientating themselves through fear and then the spiral mechanism also leads them around in circles.”

This tendency to move in spirals is not lost in the air. It is rather further complicated by the addition of a third dimension with which the pilot must cope. Professor Schaeffer’s report and the experiences of many pilots while flying through fog lead to the belief that this spiral tendency may work in the third dimension and such a compound tendency may readily cause a plane to become tilted at almost any angle while the pilot still believes himself flying on an even keel. Under such a condition, while flying in fog, it would be quite possible for the plane to be tilted at a stalling angle without the pilot realizing it.



At right: Close-up of instrument box for use with Barany chair to show illusions caused by vertigo. _Below:_ Method of using instrument box with Barany chair. Slide removed in both cases to show instruments

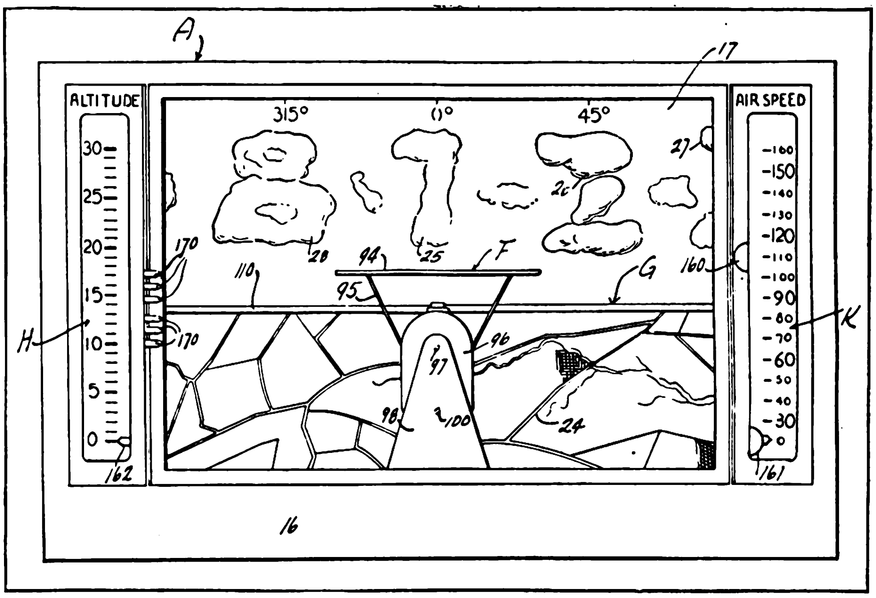
To correct this spiraling tendency and enable us not only to walk in a straight line but to maintain our equilibrium, Nature has endowed us with a number of senses, chief of which are the sense of sight, the vestibular sense, deep muscle sense, and the tactile sense. Tactile sense, or the sense of touch, is of considerable importance on the ground but in the air, with heavy clothing and within closed cabins, this sense is reduced to a minimum and plays only a minor and insignificant part and may be disregarded entirely so far as maintaining equilibrium or a straight course is concerned.

Deep muscle sense, often alluded to by pilots as “feel of the ship” or “seat sense,” includes sensations resulting from stimuli from the muscles, tendons, bones, joints, and internal organs. The pilot has been taught to lay great faith in this sense. There is no known method for accurately measuring this sense but the thoroughly trained pilot appears to develop it and interpret the stimuli to a much greater degree than others. Deep muscle sense is far from being infallible in maintaining equilibrium, however; many pilots have come out of fog to find themselves off their course, with a wing up or down, and even with the plane upside down.

The vestibular sense is derived from that portion of the inner ear which has to do with equilibrium—the semi-circular canals, the saccule and the utricle. These are considered the chief motion perception organs and have been the subject of many investigations as being of great importance in flying. One of the simple tests which have been devised to indicate the accuracy of the vestibular reactions can be made with the Barany chair, a revolving chair with control attachments.

The vestibular reactions are controlled by the semi-circular canals of the inner ear, which are at right angles to each other. By reason of their position, they are stimulated by changes of position of the individual and stimuli received by these organs are interpreted by the brain as sensations of motion. The stimulation of the canals and the reactions observed by rotation in the Barany chair are similar to those produced in actual flight, although the subject is not actually in a spiral dive or tail spin. When rotation stops, the sensation of vertigo, or dizziness, results. If the subject in the chair is questioned after a few turns, it will be found that this sensation of dizziness is actually a sensation of rotation in the opposite direction to which he is being rotated. The individual has no control over these impulses.

Although it is known from actual experience in aviation and from experimental work that the erroneous impression derived from the repeated stimulation of the labyrinth of the inner ear is subject to decrease and duration, no normal person has been known to overcome this illusion entirely. The vestibular sense, then, is one of the senses which govern equilibrium, but without the sense of sight it not only is useless but is actually dangerous because of the illusions it creates. The sense of sight is important on the ground but is much more so in the air.



Flight integrator invented by Lieutenant Carl J. Crane and the author. At the left of painted landscape is the altimeter; at right, the air-speed indicator

THIS special sense is, of course, not infallible for there are such things as optical illusions—a mirage for example—but it is certainly the most reliable. Through sight alone are we able to take bearings on our position and calculate our approximate position in regard to a given point. So long as our sight is not impaired, we may reasonably expect to remain orientated.

Equilibrium in the air, then, depends first on the sense of sight, then on the vestibular sense, deep muscle sense, and last upon the tactile sense. In flying in fog, this sense of sight also fails as there is no fixed point outside of the plane, no horizon to aid in orientating the pilot. The solution of this problem is to have absolute confidence in the flight instruments. such as the bank-and-turn indicator, the inclinometer, and the rate-of-climb indicator. In this connection an interesting psychological problem arises.

Until very recently, all flying students were taught to disregard flight instruments and trust entirely to their "flying instinct" even in fog. As a result, pilots taking the blind flying training, flying by instruments under a covered cockpit, find it hard to disregard their instinct, which they are thoroughly convinced is a handicap without sight, and to trust their instruments implicitly. The older pilots at Kelly Field taking blind flight instruction learned less easily than the younger pilots or the flying students in whom the flying instinct theory had not been so deeply ingrained.

After the pilot has been convinced that he must disregard his instinct, instrument flying is principally a matter of co-ordination. He has been accustomed to moving his hands and feet in accordance with stimuli produced by a landscape at various positions relative to the nose of his plane. In instrument flying the stimuli are produced by various dials which must be read and interpreted before the controls can be manipulated properly. This mental process causes confusion at first but can be managed so that the average pilot can bring his plane out of spirals and spins and fly a triangular course of some distance with considerable accuracy after about 10 hours of training in the covered cockpit. Flying by instruments alone is more fatiguing than ordinary flying and also requires some practice in the covered cockpit when actual fog flying is not possible to "keep in training."

Several new instruments have been developed to lessen the strain on pilots who must fly by instruments alone, of which the Sperry company's directional gyroscope and artificial horizon are two. When a pilot wishes to make a turn of 90 or any certain number of degrees, the magnetic compass is unreliable because it spins when the plane is banked. The directional gyroscope does not spin and the pilot can tell immediately when the desired turn has been made. The artificial horizon shows the pilot the position of his plane relative to the horizon, indicating the angle the plane is banked and whether it is climbing or gliding.

THE flight integrator, invented by Lieut. Carl J. Crane and myself, is still in the experimental stage but gives promise of reducing fatigue and also decreasing vertigo caused by the rotation of the plane in a spin or power dive. It consists of a miniature plane silhouetted against a landscape painted on an endless belt. As the plane turns to the right, the background moves to the left, giving the pilot watching the miniature plane the illusion of turning similar to the impression he would receive were his vision not cut off by fog or the covered cockpit, as the case may be. Skidding or slipping is indicated by tipping of the miniature plane. A narrow white band stretched across the landscape rises above or falls below the horizon to indicate that the plane is gliding or climbing.

An altimeter reading vertically will be placed on one side of the integrator and an air-speed indicator at the other. Thus five instruments will be combined in one, making it unnecessary for the pilot to "chase all over the board" to figure out what the plane is doing, and the plane's movements will be shown directly, eliminating the mental process which is one of the chief causes of fatigue in blind flying. Vertigo is also minimized by the moving screen. When the plane stops turning, the screen stops moving and the pilot is able to orientate himself in a very short time.

The value of being able to fly in fog is readily apparent. It greatly increases military efficiency to be able to fly in all kinds of weather. As for the commercial field, it will increase safety and decrease the number of trips which must be cancelled because of bad weather, principally fog. Only one problem remains—that of landing in fog. When this is solved—and indications are that it will be, in the near future—the menace of fog which has long been aviation's most formidable enemy will be conquered.

●

A railroad executive was intensely interested in the intricate details of railroad signalling systems as described in an article soon to be published. We warrant you will be, too.
—The Editor.

ELEVATED HIGHWAY TO SPEED TRAFFIC

WHAT will be the finest, and perhaps the greatest, highway of its kind in the world, is now under construction in New York City. Built along the Hudson River waterfront, this highway, which may be listed as one of Borough President Miller's important achievements, begins at the Hudson Tunnels at Canal Street and will extend to Spuyten Duyvil, a distance of 14 miles. The lower section, up to 72nd Street, will be elevated 14 feet above the street level. From 72nd Street, it will be a beautiful boulevard covering the tracks of the New York Central Railroad completely.

Ramps will be provided at 23rd, 42nd, and 57th Streets, reaching the center of the elevated roadway so that no cross traffic will occur. This will permit a speed of 40 miles an hour, resulting in a traffic capacity of 5000 vehicles an hour. Approaches will be constructed at nine uptown points, beginning with one at 72nd Street. The roadway will be 60 feet wide to accommodate six lines of traffic and will have the most modern signal system for traffic control, fire and police protection. The architectural design will take care of the esthetic as well as the practical values of the structure.

The first section between Canal and 22nd Streets is now nearing completion and may be opened for traffic before this article is printed. Construction of this section involved many difficulties, one of the worst of which was the building of concrete foundations for the 400 columns in waterfront land that was filled in years ago with all kinds of waste materials, soil, and stones.

This great structure will aid greatly in solving New York's north- and southbound, long-distance traffic problem. It is understood that the plan calls for double-decking some time in the future.

X-RAY FINGERS FEEL OUT THE ATOMIC STRUCTURE OF MATTER

By **SIR WILLIAM BRAGG, F.R.S.**

Director of the Royal Institution of Great Britain and of the Davy-Faraday Research Laboratory.
Nobel Prize Winner. Author of "Concerning the Nature of Things"

MAN, having the power to forecast the result of overcoming difficulties and the wish to try to overcome them, has devised various ingenious methods to help him in his task. Taking first of all the difficulties that depend on the inadequacy of his vision he has invented the microscope which gives him the power of seeing details thousands of times too fine to be perceived by the naked eye. The spectacles that many of us use may be looked on as making a small step in this direction.

The power over the handling of materials has been enormously increased by the microscope. It has been the chief instrument in the study of metals and alloys, so that whole new branches of metallurgy and metal working have depended upon its use. It is fundamental to the study of the minutiae of fibers, so that textile industries depend on it more and more. It is, of course, the main weapon of the biologist and the bacteriologist upon whom so many sciences rely, such as agriculture, and all the economic development of plant life. In fact the microscope has immensely increased our powers of perceiving the small things and invisible conditions which must be treated sometimes as dangers, sometimes as objects of welcome usefulness. It has widened and enriched our world.

BUT there is a point which the microscope can not pass. With its aid we perceive what is very small, but not the "very very" small. There are regions of minuteness which it can not ever penetrate. The limit is set by a curious natural barrier; natural because it depends on the nature of light. If all the small things which mattered to us were contained within the barrier, there would be no need to try to surmount it, but this is not so. Wide as the fields are which the microscope has opened to us, far wider fields lie outside its range: fields which also contain events and things of first importance. There are details of the structure of the living cell, essential features in the composition of metals, cotton, silk, rubber, paint, bone, nerve, and a thousand other things which are hidden even from the microscope, and must always remain so hidden because the failure does not lie with the skill of the optician but with the incapacity of light itself.

Let us look a little more closely at this curious fact. The process of vision begins first with the emission of radiation from some source. Without illumination nothing can be seen. The nature of radiation is in many respects a mystery, but we know enough about it to understand that we may talk of it in many of its important aspects as waves in some medium which we call the ether. The eye is an organ designed to perceive these waves. If we turn our eyes towards the source of radiation they are filled with the sense of light. If the radiation falls on any object, it is turned aside and modified in various ways. When our eyes are directed towards the object, they take in the modified rays, and we have learned by long practice to know, from these modifications, the nature of the object that has made them. That is "seeing."

THE central point of the process is the act of scattering and modification. Now waves have a certain wavelength, and common experience of such waves as may be seen, for example, on the surface of the sea tells us that an object which is very much smaller than the length of the wave has no appreciable effect upon it. The wave rolls past a cork on the surface without showing appreciable traces of modification, but a rock or the side of a steamer may actually turn it back again. In just the same way there may be objects which are so small that they can not affect a ray of light, and such objects are forever invisible in the ordinary sense. The length of the light wave which our eyes can perceive lies within a short range on either side of a fifty-thousandth of an inch. An object of such small dimension can indeed affect a light wave, but the parts of the object do not produce obvious separate effects, so that we can not do much more by the aid of light than merely detect the object as a whole. We can see nothing of its details. There are smaller objects which we can not even perceive.

Now such details and objects can be of fundamental importance, as we have already seen. What shall we do now?

The X rays break down the barrier for us, and admit us to this immense field in which we want to be. They do so by virtue of their character as light waves, 10,000 times or so smaller than visible waves, but of exactly the same nature. They have all the necessary characters for modification by the "very very" small objects on which they may fall. We have only to ask, then, how they may be used and perceived, for our eyes fail entirely to detect them.

It happens that there are various ways in which they can be registered. One of the simplest and most convenient is by the process of photography. The plate or film which is made sensitive to light can, fortunately, also perceive the X rays, though our eyes have not this double power.

So far, so good. But we should not be able to go farther were it not that nature builds her structures on certain most interesting principles. Let us look into this matter also.

WE can take the atoms as the elements of all the substances that we use or handle in any way. We know that there are some 90 kinds of atoms of which a few vastly surpass the rest in numbers; oxygen, silicon, and aluminum heading the list. A piece of pure iron contains nothing, of course, but iron atoms; the point of great importance is that the atoms are not merely jumbled together anyhow, but are arranged very perfectly according to a simple pattern which is not very difficult to picture. Suppose a pile of cubical blocks to be made so that they lie in rows in three perpendicular directions. Think of the corners of these cubes as points in space. Put an atom of iron at each corner, or perhaps one should say, at each point where eight cubes meet. Place also an atom at the center of each cube and allow the cubes to vanish. There the iron structure is complete.

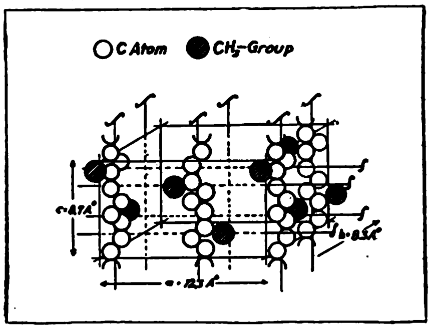
The structure of a piece of copper is even simpler. The atoms are arranged as in a pile of cannon balls, just as they are shown beside the guns in the old pictures. The structure of a diamond is rather more difficult to apprehend from a verbal description; it may, however, be grasped if it is remembered that each atom of carbon has four neighbors at equal distances from it and equidistant from each other. And so we go on to more and more complicated structures. The distances between the atoms are very small, we must remember; they vary about a mean of something like the forty-millionth of an inch. They are, of course, invisible, even in the microscope.

If a substance is such that all the atoms which compose it are arranged on one and the same pattern, so that the straight rows run through from side to side, the substance is a single crystal; crystalline character meaning, simply, perfect arrangement. Single crystals are, of course, common enough, such as jewels, salt, sugar, and a host of other kinds of substances, occurring, for example, in great frequency in the chemist's laboratory. But most substances, and especially those we handle every day, such as the metals, must be described as masses of small separate crystals. In fact a single crystal of a metal is rarely seen, and is a most curious object. A copper bar which is but one crystal throughout can be bent between finger and thumb like a piece of stiff clay. But in the very act of bending the complete uniformity disappears; the mass breaks up into small crystals. The bar loses its extreme plasticity and after a little handling becomes as stubborn as copper usually is.

THE fact is that in many kinds of crystal there are special directions in which planes can be drawn or conceived to be drawn, and the atoms on one side of such a plane can slide more or less easily over those on the other. They are called glide-planes. When the copper bar is one crystal throughout, it is easy to make this slipping occur. But when the bar is multi-crystalline, the planes of easy slipping are not the same for all the crystals, because the latter are oriented in different ways. However we try to deform the bar, there are always some crystals which resist being deformed in that particular way. And the various crystals back each other up according to some principle which we do not fully understand. Thus the properties of the bar depend upon its crystalline character.

The small crystals of which it is composed are often visible to the naked eye, and very often to the microscope. It is for this reason that the microscope has been of so much use to the metallurgist. But though the microscope can do and has done so much, it is only the X ray that can tell us the internal arrangement of the crystal, and it is only by becoming expert in the use of X rays that we can hope to unravel further the marvelous complexity of the relations between structure and properties.

If this is true of the simple metal, it is also true of the complex alloys, the properties of which are of such extreme importance in modern industry. We learn for example that iron, when treated sufficiently, changes the arrangement of its atoms to that already described as characteristic of copper. With this change its properties change also. If certain substances, carbon or manganese, for example, be added to the iron, the reverse change may be prevented, even when the temperature is once more brought back to normal. Thus the properties of iron in the second state may be retained and this is sometimes very desirable.



Courtesy of *India Rubber World* (New York)

The elementary unit of stretched rubber is found to consist of atom groups each about .00000087 millimeter in length, arranged as shown

More generally the properties of an alloy depend not only on its composition but also on the nature of the crystals which the components form, on the sizes, forms, and relative orientations and dispositions of the crystals. And this is true, to some degree at least, of all substances. In fact, when Nature builds up a substance she tries always to put the atoms together in regular order and according to a regular pattern. The crystal is always arrived at. Generally, however, the attempt to carry the structure of a single crystal through the whole of a visible mass is only partially successful and not obvious. The X rays often surprise us by showing that crystalline structure exists where we had not expected it; for example, in cotton, silk, stretched rubber, bone, and so on, and we may be quite sure that the crystalline tendency is part of the plan and contributes to the desired character of the structure.

IN conclusion, let us now consider briefly the method in which the X rays are employed to examine the crystalline structure of any body. To describe it with any fulness we should have to use the diffraction principle of physics and other principles as well. But a general understanding can be reached by readers through less accurate means. Let us remember that to make any object perceptible by the use of radiation we must allow the radiation to strike the object which then scatters and, it may be, modifies that which strikes it. The scattered rays are received by the eye or the photographic plate or some other suitable apparatus. They are registered and we use our brains to judge by the result the nature of the object.

The X rays are of short enough wavelength to be turned aside or scattered by the atoms, when longer light waves are not. A single atom can, however, do very little. What apparatus we possess can only be effective if immense numbers of atoms act together. Here is where the regularity of crystal arrangement comes in. The unit of pattern is repeated an enormous number of times even in a crystal just visible to the naked eye. Whatever one of these units does in the way of scattering, all the others do in regular order. The combined amount is perceptible, and so the crystalline character is detected.

Sometimes we have watched a flock of pigeons flying over the town roofs in the evening and have seen that, as they wheeled, the sun's rays have flashed back at the same moment from the under surfaces of all the wings. Then the flock has for an instant been a notable object in the sky. The analogy is very imperfect, as everyone will see who knows the laws of diffraction, but it may serve to illustrate the method in which the X rays are used. The rays are made to fall upon the crystal which is turned about in all ways. Then at certain moments the position of the crystal is such that all the component units act in unison and a reflected ray flashes out from the crystal of a magnitude that may be perceived.

OF course this is an indirect way of examining the structure. We do not perceive the individual atoms; we discover only their arrangements. But the knowledge so gained can be combined with other knowledge that we already possess and we have actually found ourselves able to decipher the patterns of Nature to an extent we did not dream of a few years ago. We have a new field of knowledge, a new branch of science which is in fact the physics and chemistry of the solid. Its exploration gives us unexpected but most welcome information about the fundamental design of solid materials, organic and inorganic, living and non-living. It promises to fill a wide and serious gap in our previous knowledge and to give results of the greatest interest and importance in relation to science generally and in particular to the use of science in industry.

●

In an early issue a more detailed article on the X-ray analysis of crystals, especially with regard to the study of engineering materials, will be published.—The Editor.

A FACT-FINDING FACTORY

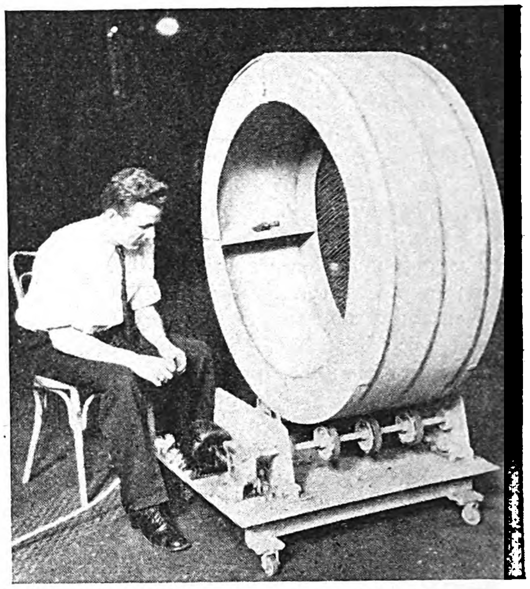
WE are frequently asked for information on testing laboratories that can be utilized for special problems by concerns and individuals who themselves do not have enough work of this kind to warrant the expense of maintaining their own laboratory. In response to the demand we present in this article the story of the availability and resources of a particular laboratory, as typical of the development along this line. Should you have problems of this kind we will be glad to give such information as we can.—*The Editor.*

THE purchasing problem is one which is always with us. It is easy to obtain prices for comparison, but unless prices are coupled with some indication of quality they do not guide efficient buying. Recognizing this fact, some of the larger industrial companies, railroads, and the government bureaus, have established laboratories for determination of the quality of materials purchased. The general public up to this time has had to be satisfied with makers' or sellers' guarantees or representations and word-of-mouth endorsements from users, in addition to such judgment and experience as are available. This problem is very much in the foreground at the present time, as witnessed by such movements as that of the Federation of Women's Clubs, the Consumer's Research, Inc., the various "institutes" maintained by publications, and so on, which endeavor to supply a service in recommending to members or subscribers the various appliances, devices, and supplies which after inspection and test can be recommended as satisfactory for purchase.

There is an observable movement also on the part of manufacturers of some classes of goods, principally in the engineering fields, to grade their own products and to issue such products under labels which the manufacturer guarantees will be affixed only to materials of a certain specified quality; for example, in recent advertising of pineapple products, a page advertisement was devoted to pointing out to the public the marks upon the cans which denote the various grades supplied. Some of the lumber manufacturers are guaranteeing the qualities of the gradings of lumber which they identify by branding the grade upon each piece of lumber.

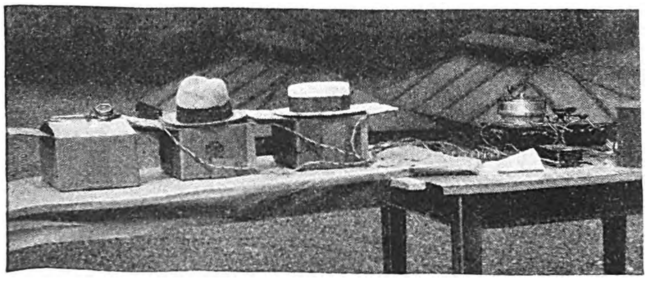
THE real difficulties in this situation are that first, testing is expensive; and second, that the expense of testing is justified only when the quantities at stake are large enough; for example, it would not pay the individual purchaser of an electric refrigerator to have tests made upon all the existing types for the purpose of discovering whether he is purchasing the most efficient device for home use. Such a procedure would cost tens of thousands of dollars while his expenditure for the refrigerator would perhaps be 500 dollars or less. But if the purchaser is buying many units, or if there are many purchasers who wish this information, then the testing can be combined so as to make it not only an economic possibility but a really profitable proposition.

Acting on this premise, the Association of Edison Illuminating Companies over 30 years ago pooled some of its testing problems, and Electrical Testing Laboratories is the outgrowth of this co-operative effort. The people behind the laboratories have been farseeing and have equipped the institution so that at the present time it is an organization open to the public in general where testing equipment and experts are available for investigations of many diverse problems and the equipment provided is very extensive and complete.

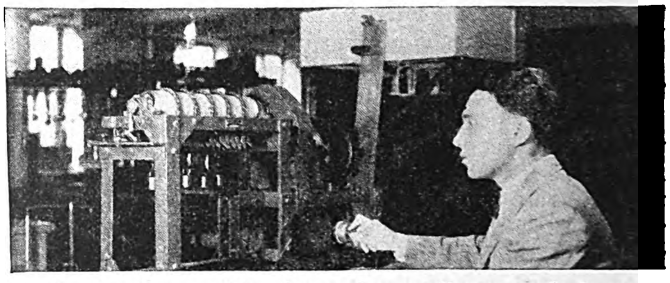


An electrically operated tumbling barrel ready to test the appliance plug on shelf

It is true that the bulk of the tests and investigations carried on at the laboratories are electrical in character but many of these involve problems outside the electrical field which demand collateral investigations. For example, the investigations of the quality of power cable bring in the study of the composition and properties of lead, copper, paper, and insulating oils, all of which are the component parts. In addition these components must be subjected to mechanical tests for strength, effect of distortion, and so forth, and electrically, tests must be made to determine the conductivity of copper and the electrical strength of the insulation. Studies must also be made of the effect of heat and cold, the heating effect and consequent deteriorating effect of time, heavy current, and so on, so that it is



A straw hat maker wanted his hat tested to find the heat inside as compared with that within a felt hat



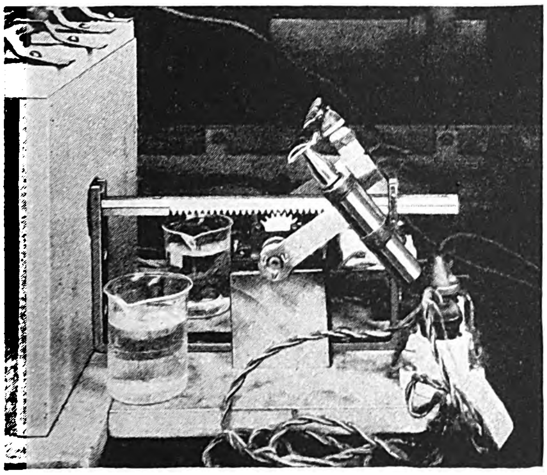
An abrasion machine for testing appliance cords is an example of machines designed to test to destruction necessary to provide very large and expensive equipment and even more important, a staff of experts who can bring to bear on the testing problems a wide variety of experience.

At the present time, these laboratories occupy several buildings situated at the corner of East End Avenue and 80th Street, New York City, comprising 66,000 square feet of floor area. There is a force of 325 people, 225 of whom are engaged in work at the main laboratories and 100 who are traveling or resident inspectors located at various factories from Boston, Massachusetts, to Oakland, California. Traveling inspectors visit practically every state.

THE magnitude of the work which is done can best be realized when it is explained that tests made by this laboratory in the past year covered the inspection and testing of over 300,000,000 incandescent lamps, 9,000,000 feet of power cable, over 1,000,000 porcelain enameled steel reflectors, design tests of all of the automobile headlamps in use in 20 of the eastern and central states, besides some 8000 miscellaneous tests for large purchasers, manufacturers, and consulting engineers covering many varieties of electrical apparatus, and appliances. Many thousands of electrical safety devices, such as rubber gloves, linemen's protectors, overshoes, leggings, insulated tools, and so forth, are regularly inspected and tested.

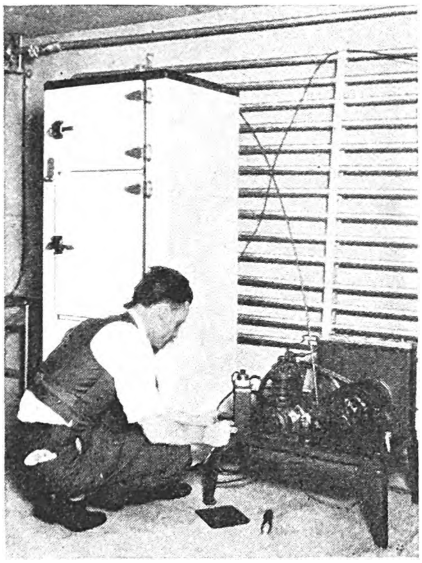
In the chemical department analyses have been made upon such diverse materials as steel, coal, paper, soaps, typewriter ribbons, pencils, insulating varnishes, oils, gasoline, boiler compounds, water, and fuel oils.

During the past year, a very interesting investigation has been carried on for the electric light and power companies which comprise the Association of Edison Illuminating Companies, on electrical appliances which are used in the homes served by these companies. Samples of all types of electric flatirons, simple and automatic, over 50 different models of electric ranges, 150 appliance plugs, 100 types of appliance cords, many percolators, electrical refrigerators, toasters, and so forth, are being tested, in many cases to destruction, to find out their serviceability, so that these power companies may be in a position to recommend to their customers appliances which give good efficient service for long periods with a minimum of repair and readjustment.



A machine that will substitute for a lot of shaves in determining the life of a safety razor

The photometric department performs many services. In addition to the measurement of incandescent lamps, it makes tests upon lighting fixtures, search-lights, flood-lights, and flashlights. Tests are also made by this department on the illumination of artificially lighted premises such as offices, banks, railroad terminals, and lighted streets. It is sometimes called upon for tests of artificial and natural lighting, in connection with damage suits, both personal and as the result of restriction of natural lighting. Many tests of this kind are also made in connection with the determination of the validity of patent claims.

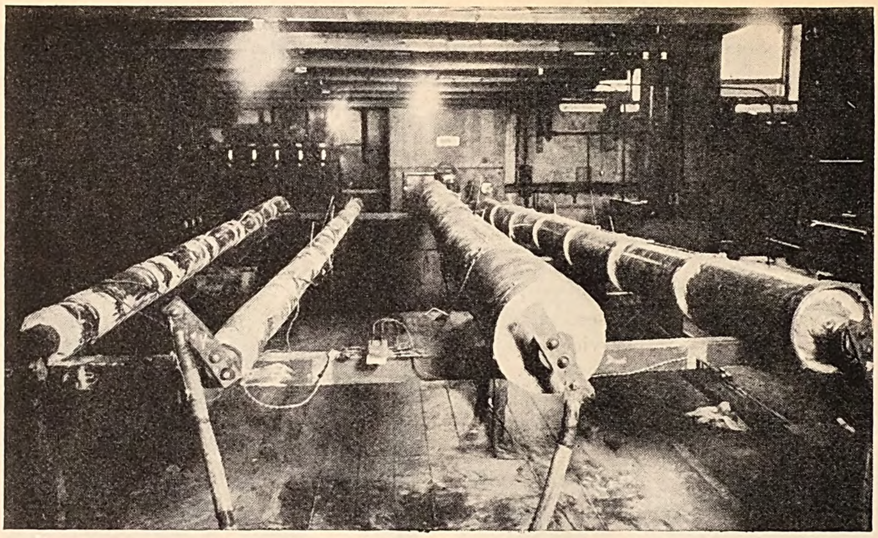


Testing an electrical refrigerator unit in a specially equipped room

Perhaps the most interesting examples of testing are those which may be termed "freak" investigations. For example, a dead goldfish was submitted by a hotel in New York with a request that a determination be made of the amount of copper sulfate in the body of the fish, it being thought by the client that the fish was poisoned by the absorption of copper sulfate from a copper tank in which a large number of fish were kept in the hotel lobby. A manufacturer of cigarettes submitted a number of brands of cigarettes to determine the heat of burning the cigarettes under normal smoking conditions in order to prove an assumed superiority of one brand. Three brands of golf balls were tested for relative resiliency. Samples of procelain-enameled iron were submitted for tests of deterioration of the enameling under acids which might be encountered when metal table tops are subjected to ordinary kitchen usage. A manufacturer of straw hats submitted his product for test in order to find the relative heat inside the straw hat as compared to the heat inside of felt hats, the hats being exposed to direct sunlight.

Filling rubber gloves with water as part of an electrical leakage test

IN this category also may be placed the tests made for investors who wish to know something about the value of an invention or process in which they are considering investment of capital. For example, a gasoline substitute was submitted, which upon analysis was found to be composed of a fair grade of gasoline with a small admixture of lubricating oil to give it color. A rechargeable dry battery was found to be simply a good dry cell of a standard type with a new label substituted. A storage battery compound, warranted to increase the capacity of any lead-sulfuric acid storage cell, was found to be made of corn starch which had no beneficial effect. A new type of airplane cloth reinforced with very light but strong steel wires designed to add materially to the strength of the material was subjected to mechanical tests. A so-called "electric therapeutic" device, which it was alleged had effected marvelous cures of rheumatism and sci-

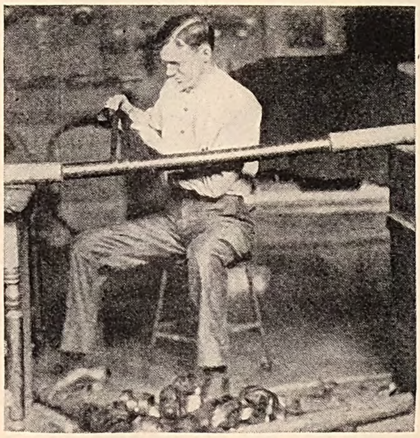


A view of part of the mechanical laboratory where tests for thermal conductivity, valuable to manufacturers, are being carried out on various steam-pipe coverings

atica, proved upon investigation to be a nickel-plated cylinder filled with sealing wax.

It is not only in exposing obvious frauds that these laboratories function. These constitute but a small though interesting fraction of the work of the laboratory. It functions often in connection with the development of processes which are brought to satisfactory and successful results. There may be cited in this class the Klaxon automobile horn which was designed by a client of the laboratories, working in a private shop and submitting from time to time the results of his labor for tests. Several manufacturers of insulating varnishes have used tests developed in the laboratories in connection with their own experiments in the blending of varnishes not only to increase the insulation resistance of their varnishes, but also to increase the length of time that the varnished cloth or paper made up with their compounds would remain pliant. A manufacturer of diffusing glassware, by continued experimentation, designed a form of translucent glass which transmits a considerably larger amount of the light falling upon it than was apparent in the first samples submitted.

DURING the World War, manufacturers of star shells for lighting battlefields at night, by constant test and experimentation of various mixtures, increased the illuminating power of such shells from 10,000 candlepower with a burning period of 30 seconds to over 100,000 candlepower with a burning period of a minute and a half, eliminating also a great deal of the flicker which was characteristic in the first samples. In all these cases, the tests were made for the manufacturers upon samples which they fabricated using the formulas which had been suggested or proved by repeated tests.



After a cable has been tested on over-load, insulation is inspected

As was indicated previously, this institution is called upon from time to time for tests in connection with legal controversies. In such cases, the laboratory prefers to be retained if possible by both sides and to make the results of its tests available to both parties in the action. As examples of this type of service, there may be cited a test which was made to determine the electrical resistance of a pair of shoes which had been worn by a lineman who had been killed by an electric shock; the testing of a street lighting installation to determine the compliance to specifications of the street lighting equipment used by a power company; the measurement of natural light reaching the windows of a building; the measurement of the loss of light occasioned by changes in the construction of the Manhattan Elevated Railroad in New York as a basis for determining the compensation to be paid to owners of adjoining property. Very often in such cases the variation in natural lighting is so great as to make it impracticable to obtain complete measurements on the actual premises. In such cases, a few check measurements are made in actual position and a scale model is constructed which is artificially illuminated. An exhaustive study of the model is made, in this way eliminating all the variable features except those that are in question.

IT is to be expected that an organization of this kind is called upon from time to time to make tests for inventors whose hopes for success are greatly in excess of the merits of their inventions. In such cases, the attempt is made to dissuade them from spending money foolishly. In the 34 years of existence of this institution, there have been submitted perpetual motion machines, direct-current transformers, lighting appliances which are designed to multiply the total flux of the original lamp 100 times, electric generating machinery for producing more than 100 percent of the power put in, mechanical and electric water heaters of 200 to 300 percent efficiency. The problem in these cases, a diplomatic one, is to dissuade the inventor and at the same time to convince him that the laboratories are not the agent of the trusts which are engaged in keeping back improvements which might revolutionize industry and thereby destroy invested capital.

Many more instances of the variety and interest of the work might be given but the bare outline which is presented indicates the wide variety of effort which is characteristic of the testing problem, the diversity of the clientele which must be served, and the value of constant continuous research as an aid to betterment of conditions, the safeguarding of human life and property, and the encouragement of progress.

WHAT IS A QUANTUM?

By **PAUL R. HEYL, Ph.D.**

Physicist United States Bureau of Standards
Author of "The New Frontier of Physics"
Contributing Editor *Scientific American*

"DO you remember," said the visitor, "when I came here some time ago, asking you to tell me what an atom was?"

"Yes," said the scientist, "and I could not do it."[1]

"Perhaps you did better than you thought. Now I have another question to ask you."

"I hope it is something easier this time."

"Well, it isn't about Einstein. I only want to know what the quantum theory is all about. What is a quantum, anyway?"

"You do not seem to be getting any more moderate in your demands," said the scientist. "How much do you know about it, to begin with?"

"Very little. All I have gathered is that a quantum has something to do with energy, and that it is considered a very important thing nowadays."

"Then so far you have nothing to unlearn," said the scientist. "We may as well start at the beginning. The quantum theory is a good illustration of the fact that history is prone to repeat itself as well in scientific thought as elsewhere."

"How is that?" asked the visitor. "Is not science always progressive?"

"Yes, certainly; but some parts of it progress faster than others, principally because they had an earlier start. Our ideas regarding energy, for example, have recently undergone a change similar to that suffered by our concept of matter a great many years ago."

"In what way?"

"MATTER has been studied by man for thousands of years. It was at first supposed to be continuous in its structure, as indeed it appears to be; but our present idea is that it is really discontinuous in its structure, built up of atoms and molecules and actually consisting principally of empty interspaces. This concept grew up gradually, but we may perhaps take the work of Dalton at the opening of the 19th Century as marking a time when the atomic theory was rather generally accepted."

"Yes," said the visitor. "I have heard him called the father of the atomic theory."

"Still," continued the scientist, "there were men of scientific standing all through the 19th Century who clung to the older continuous theory. The last great disbeliever in atoms, Ernst Mach, died as lately as 1916."

"You surprise me!" said the visitor. "I did not know that the past projected so far into the present."

"Such are the facts of the case," replied the scientist. "This last opponent of the atomic theory lived to see the doctrine against which he so hopelessly fought conquer not only the domain of matter but also that of energy."

"Are there then atoms of energy?"

"Something very like it; only we call them quanta. Energy is a comparatively new concept, dating back only to the middle of the 19th Century. When it first took shape it was regarded as continuous."

"Of course," said the visitor. "I have always understood it that way. The continuous stream of light and heat from the sun illustrates that."

"How do you know that the stream of light from the sun is continuous?"

---

[1] Heyl: *Scientific American*, July 1928.

“Why,” said the visitor, “there are no dark spaces perceptible—but then,” he added with a smile, “I suppose the same might be said of matter.”

“Exactly. The cases are parallel. For good reasons we believe in the existence of atoms, though no one has ever seen them; and also for sufficient reasons we have come to recognize the discontinuous nature of energy. History is repeating itself in scientific thought.”

“So that is what the quantum theory is all about!” said the visitor. “But how did this change in our ideas of energy come to pass?”

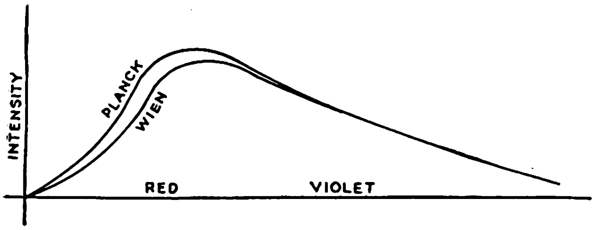
“Very much as the atomic theory of matter came to supersede the continuous theory. One was found to fit the facts of experiment better than the other. The historical parallel is perfect.”

“This is getting interesting,” said the visitor. “Tell me how it happened.”

“It began over 30 years ago, shortly after the discovery of the X rays. It was soon found that air or any other gas exposed to the passage of X rays became electrically conducting. Bring a charged electroscope near an X-ray tube in action, and the divergent gold leaves will collapse at once; the charge leaks away through the air, which under normal conditions is one of the best of insulators. It was found that this conducting property of the air was caused by the fact that some of its atoms were split up by the X rays into two parts, bearing opposite electrical charges, though the original atom was electrically neutral. This is called ionization of the gas. And the surprising thing was that so few of the atoms were ionized. Although the gas was swept through and through by successive waves of X rays, only about one atom in a million million was thus broken up.”

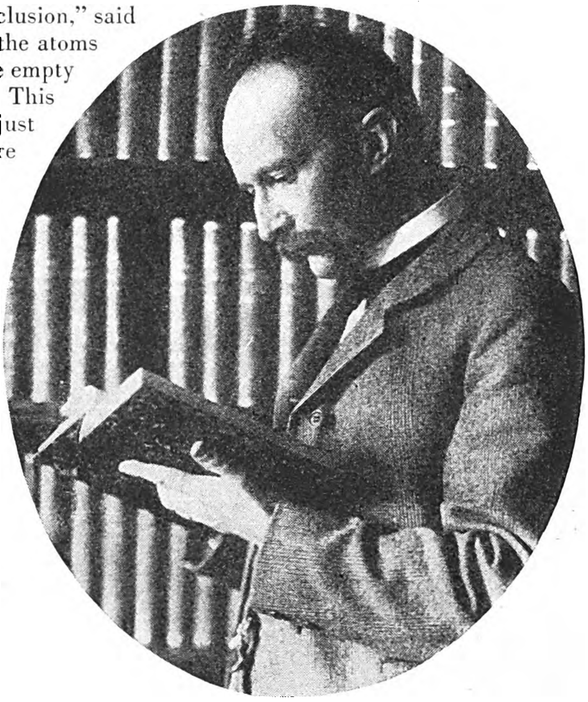
“I should say,” said the visitor, “that that net must have had a lot of big holes in it.”

“Exactly,” said the scientist, smiling. “Put into scientific language, that was just what J. J. Thomson thought about it. He was forced to the conclusion that the advancing wave of X rays was not uniform, but of a beady or lumpy structure, the energy of the wave being concentrated mostly in spots and spread out thinly elsewhere. His explanation was that only these intense spots of energy were equal to the task of splitting up an atom, and from the fact that so few atoms were ionized he reasoned that the wave front must be made up principally of thin places.”



Distribution of energy in the spectrum. The curve marked “Wien” represents the best that classical theory could do. The curve marked “Planck” is that given by the quantum theory, and fits much more closely the curve obtained by experimental work

“A perfectly natural conclusion,” said the visitor. “But where do the atoms of energy come in—and the empty spaces between them? This thick-and-thin structure is just as continuous as if it were uniform.”



A rare photograph of Max Planck, who has been called the Dalton of the 20th Century. His law of radiation (1901) asserts that “radiant energy” is emitted and absorbed in integral multiples of indivisible quanta of energy. For his contributions to science he was awarded the Nobel Physics Prize in 1918

“True enough,” answered the scientist. “The quantum theory carries things to the limit of *supposing* all the energy to be concentrated in the spots with the interspaces empty. This extreme the X-ray evidence that I have mentioned did not require, and it is a principle of scientific thought that we are never to assume more than is necessary to explain the facts. It required evidence of another sort to force us farther. This next step is due to Planck, who in 1900 suggested the modern form of the quantum theory.”

“On X-ray evidence?”

“No; the evidence was of a different nature. It had to do with light. Theory and experiment had, in a certain field, failed to agree. Planck brought them into agreement by supposing energy to be atomic in its structure.”

“Was the discrepancy between theory and experiment so serious as to require this radical step?”

“It would have been serious, no matter what its magnitude, provided that it was great enough to be sure of; but judge for yourself. What happens when a piece of iron is heated?”

“It becomes red hot.”

“And then—?”

“Yellow, and finally white hot.”

“But suppose I should tell you that it should not act that way; that on theoretical grounds it ought to show a blue color from the start, no matter how hot it was?”[2]

“I should consider that a very serious discordance. Was it really as bad as that?”

“Yes, the classical theory insisted on predicting rays more intense than those actually observed, and of the wrong color. To take an analogy from sound, the emission of light from a gradually heated body is something like what happens when we press down and hold down all the keys of an organ in succession, beginning at the lowest. To the lowest frequencies would be added successively those higher in the scale, until at last the whole range (or spectrum) would be present. But the classical theory demanded that the high frequencies should appear from the start, and always be more intense than the lower ones.”

“And Planck’s theory straightened out this discrepancy?”

“Perfectly. On the quantum theory we suppose that energy is made up of atoms or quanta. Less than one quantum can not be absorbed or emitted by a body, and all emission or absorption must be in multiples of this fundamental quantum.”

The visitor looked blank.

“It is something like our money system,” continued the scientist. “The smallest amount we can pay anybody is one cent, and any amount that changes hands must be a multiple of one cent. Now suppose your income was small, say one cent per hour, and that your creditors were pressing you. All you could do would be to pay out one cent now and then. This corresponds to the case of iron slightly heated. The influx of heat is not rapid, and the iron can emit only quanta of low frequencies—

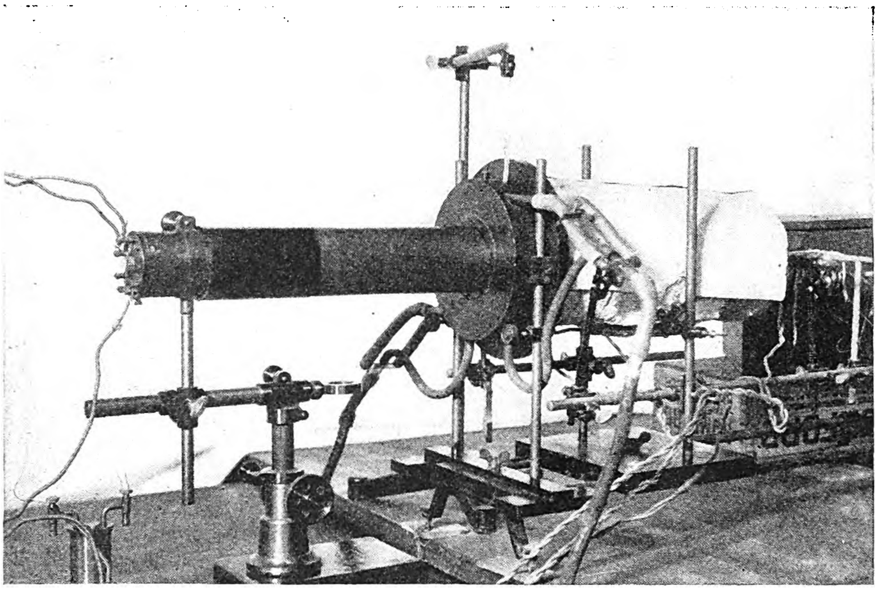
---

[2] A. H. Compton: *Physical Review Supplement*, July 1929, page 74.

coins of low value. If your income was more rapid you might be able to pay out nickels or even dimes occasionally along with the cents. So as the iron is more intensely heated it is able to emit quanta of higher frequencies along with the lower ones."

"Is there only one fundamental quantum?"

"No, matters are more complicated than that. It is like having several different kinds of currency circulating together; English, French, German, as well as our own. The smallest coins of each kind would be different in value, and not exact multiples of each other; and we would have a series of multiples of each kind in circulation together. There may be many quanta of different frequencies, and a radiating body may emit multiples of any of them."



Apparatus for determining the Stefan-Boltzman constant of radiation, which is connected with the distribution of radiant energy in the spectrum of hot bodies

"But nothing but exact multiples? No fractional quantities?"

"Apparently not."

"Why is that?"

"We do not know."

THE visitor was silent for some moments. Then he said:

"The only reason why I can not pay out or receive anything but exact multiples of one cent is because the mint in this country does not coin anything else. It is not a limitation on my part. In England I would not find the slightest difficulty in paying out multiples of a half penny, although that is not exactly equal to one cent."

The scientist nodded approvingly.

"I agree with you. This curious restriction to multiples of a quantum in exchanges of energy may be a limitation arising from something in the structure of the molecule, or it may be that Nature's mint coins nothing but even multiples of a quantum. I am inclined to the latter view. The fact that a molecule can actually emit almost any quantity of energy that can be imagined, provided that there is a fundamental quantum of which it is a multiple, suggests that the limitation is not in the molecule."

The visitor smiled.

"I have read that Sir John Herschel once compared atoms to manufactured articles, because of their close similarity. Now it seems that we must think of energy likewise. Nature coins quanta and multiples of quanta, and it is against the law to clip or debase the coinage."

"Yes," said the scientist. "A quantum seems to be indivisible."

"Just as it used to be thought the atom was."

"Your point is well taken," answered the scientist. "But up to the present we have no experimental evidence requiring us to assume the contrary."

"Well," said the visitor, "to return to my original question, what is a quantum? If we magnified a light wave sufficiently what would we see?"

"It is no more possible to magnify a light wave sufficiently to perceive its structure than to magnify matter enough to see the molecules; but if we could sufficiently enlarge an advancing front of a light wave it would probably appear as a lot of bright specks on a dark background."

"That rather suggests Newton's corpuscular theory of light."

"Quite so, except for the important difference that each quantum is vibrating with a certain definite frequency."

"And what is it that vibrates? What is a quantum?"

"Nobody knows. Some have thought it to be a little train of waves, something like a dart; others have pointed out that it is more probably a three-dimensional affair. We have no more idea of what a quantum is than we have of the nature of an atom; and, as you know, our concept of an atom is a good deal like a moving picture."

"Three dimensional?" said the visitor. "How big is a quantum?"

"That question has been asked by others. The answer seems to depend on the direction by which we approach the question. For instance, a quantum of light must enter the eye as a whole to excite vision. Less than a quantum will not do. And yet, from astronomical considerations, a quantum of starlight must have about the dimensions of a barrel."

"And all that has to get into the pupil of the eye? That is something like packing the genie into a bottle."

"We frequently encounter contradictions of this sort in the early stages of scientific thinking about any subject. It indicates usually that our ideas are as yet incomplete and fragmentary. We must attain a broader and more general concept, of which these contradictory pictures may be seen to be special cases."

"The philosophers of old," remarked the visitor, "used to say that Nature makes no jumps; but what with atoms and quanta it begins to look as if discontinuity was the first law of Nature."

"There is a curious consequence of this discontinuity," said the scientist, "which probably you have not heard of. Suppose that you took a pocket full of pennies and went to visit an orphan asylum, and on your arrival found that there were more children than pennies. Even allowing only one cent to each child some would have to go without. But perhaps you see what I am coming to," said the scientist, breaking off as the visitor began to smile.

"Not exactly," said the visitor. "But I can see that for 'children' we must read 'molecules' and for 'pennies', 'quanta of energy.' "

"EXACTLY," said the scientist. "We have a pretty good idea of the energy value of a quantum just as we have of the size and mass of a molecule, though we can not tell just what either looks like. And it works out in this way: the total heat energy in a body may consist of fewer quanta than the number of its molecules. This is possibly the case in red hot iron. It is a curious thought that in such a body there may be molecules here and there as devoid of energy as if the whole body were at absolute zero."

"Poverty and riches rub elbows among molecules as with men," said the visitor. "Very human little fellows, these."

"Perhaps," said the scientist, "the molecules of which we are made up might view the matter oppositely, and with more reason."

FEEDING THE CREW OF A BATTLESHIP

By **JOHN DONALD THOMPSON**

Chief Boatswain, U. S. S. *West Virginia*

THERE are, no doubt, many hungry people within the broad domain of Uncle Sam, but if so, certainly they are not to be found upon his fighting ships. Food, selected and inspected, the finest in the world, is most plentiful. Carefully guarded, refrigerated, cooked hygienically and served under supervision from the cleanest of dishes fresh from electrically operated dish-washing machines filled with distilled water, boiling hot, the food reaches the men in its most tempting condition.

One hundred and ninety turkeys; more than 2000 pounds for only one meal! It sounds like a great deal, but it is only for a holiday, the fourth of July or Christmas, dinner to which must be added all the other good things that go with such feasts. The men, the boys that man the fighting ships are, most likely, far from home, but otherwise the holiday meal is just as tempting and complete. Then, to this must be added the novel surroundings of life on board ship and an appetite whetted by regularity, salt air, and wholesome exercise. On the fourth of July, at noon, 2000 pounds of turkey disappear from the plates of the eager boys as if by magic; the well rounded out menu is reproduced on this page.

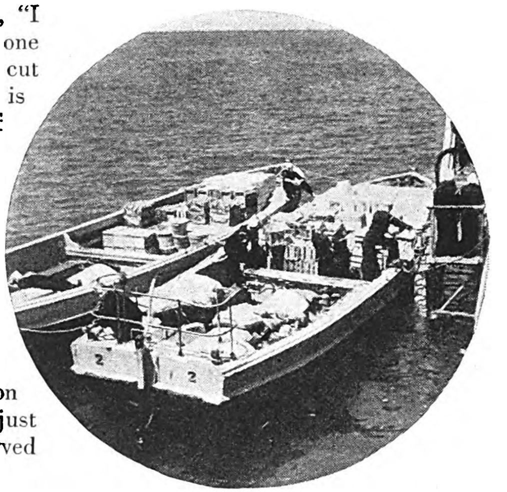
I passed by the metal-screened door of the butcher shop where the head butcher was carefully explaining to a lady visitor (and as many other visitors as could crowd into the doorway) his daily labor in providing the meat portion of the daily ration for 1300 men.

"Why," she exclaimed, "a ham will last us ever so long, even if we are all at home—and every one of us is a hearty eater!"

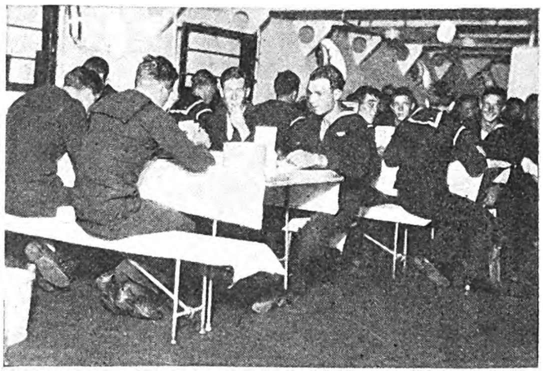
"Yes'm," he patiently explained, "I guess so, but 50 hams makes just one meal for us. It is boiled, then we cut it up and serve it out; none of it is ever left over. Lots of other stuff goes out from the issue room and the galley up forward. Beef? Oh yes, we use lots of beef. We cut up about 850 pounds of hind quarters into beef steak with this machine for one meal; then it is fried in the galley. Seven hundred and fifty pounds for veal cutlets and only 500 for stew. Six hundred pounds of halibut makes the noon meal on Friday; besides this, just about every sort of meat is served at various times."

Lots of times when I pass the butcher shop I look in through the large round port hole; usually they are all busy cutting up meat or cleaning and polishing up the shop.

WE have thousands upon thousands of visitors from every state in the union; no matter what port we may happen to be in. Many men are detailed as guides to show them about the ship and make them feel at home. Sometimes I act as a guide myself, though not so often now, and it seems that all visitors, especially women, invariably ask to be shown, the "dining hall, the kitchen, and the pantry." So we take them down below and show them the great deck spaces hundreds of feet long and from 30 to 50 or more feet wide; this, they are told is the "dining hall," or more simply, the mess deck. From here, they are shown into the large galley that is lined with huge oil-burning steel ranges and steam-jacketed kettles manned by a dozen white-clad cooks busily preparing the next meal, the savory odors of which invariably bring forth exclamations of delight. This, they are informed, is the kitchen. They leave this attractive place of activity, of pleasing odors, with many a backward glance and exclamations of wonder.



Boxes, bags, crates: two 59-foot motor launches at the gangway with provisions



All photographs by the author

Any doubt that our sailors are well fed will be dissipated by one glance at the menu at the left and at the healthy, happy faces in the illustration above. During such a holiday meal, 2000 pounds of turkey disappear from the plates of the sailors

INDEPENDENCE DAY

4th of July, 1930

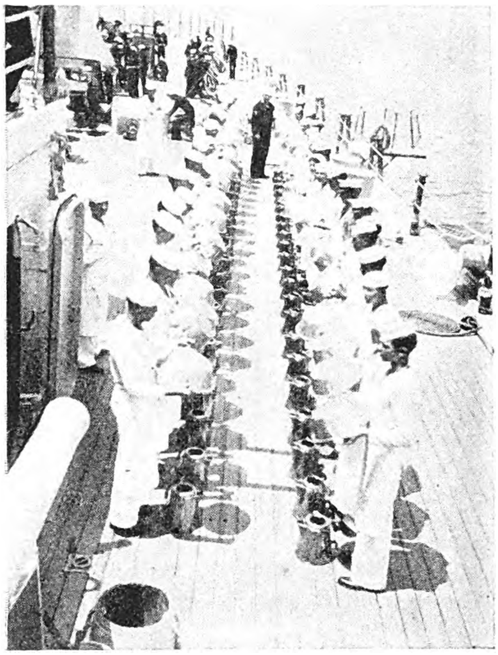
Creole Potatoes **Buttered Squash** **Sweet Corn on Ear**
Sunshine Cake, frosted **Blackberry Pie**
Neapolitan Ice Cream
Cigarettes
Coffee

"Now," confided one attractive young matron, "I must see the pantry. They may cook in a galley, but there must be a pantry." So the party was shown into the compact and abundantly stocked issue room with its snow white tiled deck and glistening shelves, its rows of polished bins, barrels of pickles and vinegar, rows of sacks of sugar and beans, and the untold number of things that go to fill the pantry, or as we call it, the "issue room."

"And this," said the guide to the attractive young matron, "is the pantry."

After marching forward on one deck and aft on another without having seen anything resembling a dining table, the party is sure to ask where the tables are. They are then pointed out, neatly stowed in pairs on iron racks overhead between the beams. Each table is fitted with folding iron legs, as are the little benches that fold up and are stowed on top. When taken down and set up for use, they seat 10 men quite comfortably. One mess consists of 20 men using two tables and served by one mess cook, or a total of 21 men. The number of messes varies somewhat, but averages around 65.

The mess cook, who does no cooking at all, brings the food from the galley, the bake shop, and the issue room, and the dishes from the scullery. He also washes the knives and forks, besides cleaning up the deck and a considerable portion of the paint work in the immediate vicinity. Then once each week he has to take the tables up on deck and scrub them with sand and bleach them out in the sun.



On deck in bright sunlight, the daily inspection of shiny coffee pots and dish pans

If it so happens that a mess cook is good in bringing down "seconds" from the galley, the boys give him a lift now and then with the work and of course help in stowing the tables overhead. After a period of time, usually three months, the detail is relieved. Sometimes they stay for many months on this duty and seem to like it. When I was a mess cook, food was rather scarce and I was well pleased when I went back on deck.

The dishes are washed in a scullery where the far famed "scullery maid" would have found delight, for in their metal racks like eggs in a carton, the dishes for 1300 men are washed and stowed in from 14 to 19 minutes with an electrically operated dish washing machine having a crew of four men and one checker. After having been washed they are stacked, in their own racks, upon shelves, all ready for the next meal.

Visitors note with satisfaction the "spud coxswain" and his gang of a dozen or more men as they busily prepare vegetables in the vegetable-locker adjoining the galley. About one ton of spuds, or potatoes, are prepared each day. Two electrically driven peelers make quick work of about 20 sacks, then each one is gone over by hand for spots. If required, they are passed through the slicer for French fry, or go into the steam-jacketed kettles to make the well known mashed potatoes. Celery, lettuce, cabbage and, in fact, just about all vegetables are prepared only by the crate.

IN looking over the accounts I note that the boys have used in one half month, 10,000 pounds of cantaloupe besides 8000 pounds of watermelon and 1500 pounds of various berries. Eight hundred pounds of green onions must have been a lot of onions, but it went along with 10,000 pounds of green corn; 1500 of lettuce; 2000 of cabbage and a like amount of celery; 1400 of ripe tomatoes; and 1000 of bell peppers, and numerous other items that would appear small, being, as they are, under 1000 pounds. Fruit is served much more than is commonly believed —practically every day if possible. If fresh fruit is not available, the canned article is used.

In the preparation of vegetables, 20-gallon steep-tubs are used. In the cooking, either the 40- or the 60-gallon steam-jacketed kettles are used. The same kettles then come in handy when cooking macaroni, stew, beans, and numerous other standard articles of diet while the long row of steel, oil-burning ranges is principally used in the preparation of meat. One of the principal troubles encountered with meat is that it has to stand for some time after cooking before it is served; this has never tended to improve the quality of meat.

Having passed through the wide, white-tiled galley with its long rows of huge kettles and ranges, the visitor comes to the coffee pot. A shining copper urn of 120-gallon capacity, majestically it stands beside the galley door. Its eager daily visitors are legion, for be it known that "Jamoke" has ever played a most important rôle in the daily life, and it might be said, the night life, of both the old-time shellback as well as the sailors of the modern man-of-war.

COFFEE is served out to the crew at 5:30 each morning; then once again for breakfast and at noon. Tea or cocoa is usually served with the evening meal, but coffee drinking is general throughout the ship both day and night, especially by the men on watch. The daily inspection of coffee pots is a pretty sight. The mess cooks are lined up in formation in spotless white uniforms with aprons, each with his shining coffee pot and bright dish pan.

Once outside the galley, the door of the bake shop stands invitingly open, while from within issue tempting odors of newly baked bread mingled with that of spiced pies and delicious pastries. Inside this Aladdin's shop, huge electric bake ovens silently perform their tasks while the electrically driven dough mixer vies in slow rhythm with the lively tune of the cake mixer.

Stacked in neat array against the steel bulk-head, ready at hand, you observe many tons of flour and sugar besides the ample stock of ingredients that go to make up the bread and pastry shop of the ultra-modern man-of-war.

For the time being the visitor is apt to think that the navy is simply a place ingeniously equipped for the preparation of food, for hardly has he passed out of this novel bakery when he is confronted with another galley entirely different from anything seen before. This time the roaring ranges are presided

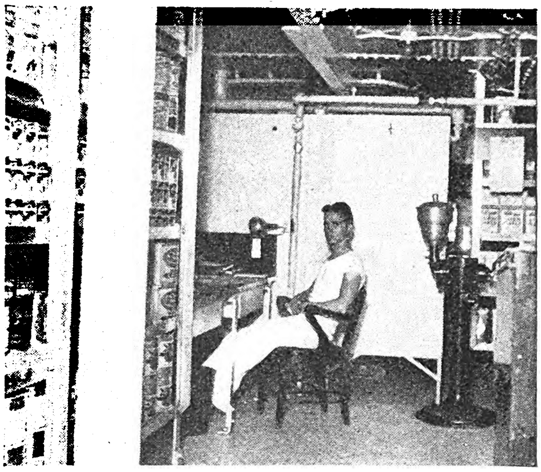
The dishes are stowed in metal racks like eggs in a crate. After being washed, they are stacked, in their racks, ready for the next meal

over by men of different races: Filipino cooks, Negro cooks, and sometimes a Japanese. This is the officers' galley where these mixed races deftly ply their art. From this galley, a sparkling gem of efficiency, go the very choicest foods in the world to the officers' mess.

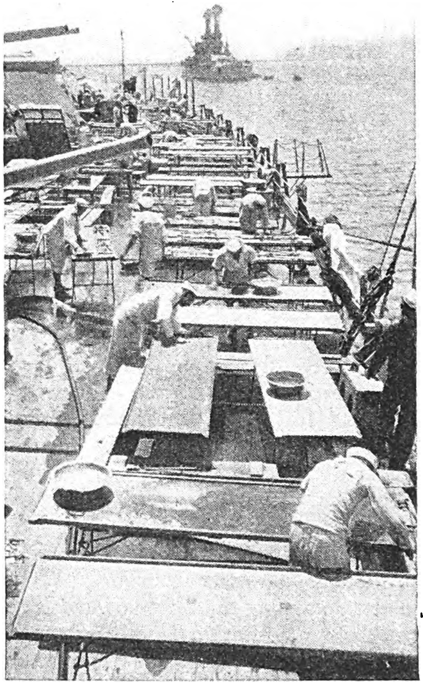
When necessary to provision ship, usually once each month, a day is set aside for that purpose. About 100 tons of provisions, consisting of both fresh and dry stores about equally divided, are taken on board that day. About 50 tons are tinned and sacked stores while the rest is all of the fresh or perishable variety. The meats are frozen and go into the refrigerator while most of the fruits go into the chill room with the eggs, the butter, and the cheese.

SOME of the articles loom rather large. Of beef there will be 20,000 pounds and of sugar a little more. Flour soars to 30,000 pounds while potatoes top the list and run between 40,000 and 50,000 pounds. Coffee keeps well above 1500 pounds; pork loins run about 4000 pounds while one ton and a half of hams skimp sadly by. Bologna and "franks" are slightly less and 1500 to 2000 pounds of chicken or turkey simply means one meal. Five thousand pounds of butter together with 3000 dozen eggs fried with 1500 pounds of bacon finishes a good many breakfasts to the fighters of the nation's first line of defense. Six thousand cans of milk are used each month in cooking and in coffee, while 600 pounds of yeast finds its way to the bake shop.

On one day each week a working party of some 25 men are engaged in bringing up provisions from the well-stocked store room to the commissary issue room. This issue room presents a most imposing appearance. It resembles a fully stocked grocery store minus any perishable articles except fruit and is presided over by a specialist in commissary work, who is a diplomat capable of keeping the crew contented and the captain satisfied—a task of no mean proportions. An army is said to travel on its stomach; a navy, then, might be said to sail on its stomach with the commissary steward as the chief pilot supported by his ample store rooms filled to capacity with practically every known article of food on the market, in the finest condition, ready to weather the storm.



The Issue Room and the desk from which all orders of food are issued. The ship's pantry



The mess tables are scrubbed with sand and bleached in the sun on deck

BILL OF FARE *for the* GENERAL MESS

Beginning June 30th, 1930

	BREAKFAST	DINNER	SUPPER
MONDAY	Cantaloupes, Corn-flakes, milk, sugar. Scrambled eggs, braised bacon. Lyonnaise potatoes. Vienna rolls. Bread, butter, coffee.	Vegetable soup. Crackers. Grilled beef steak, onion gravy. Mashed potatoes. Steamed peas. Shirred lettuce. Apricot pie. Bread and coffee.	American chop suey. Steamed rice. Boiled sweet potatoes. Tapioca-fruit-pudding. Bread, butter, tea.
TUESDAY	Cantaloupes. Boiled hominy grits, milk, sugar. Fried pork sausage, pan gravy. Creamed potatoes. Parkerhouse rolls. Bread, butter, coffee.	Cream of tomato soup. Saltines. Pot roast of beef, brown gravy. French fried potatoes. Boiled cabbage. Sliced tomatoes. Mincemeat pie. Bread and coffee.	Fried hamburger steaks. Worcester gravy. Boiled new potatoes. Macaroni-Italian. Beet-onion salad. Chocolate pudding. Bread, butter, tea.
WEDNESDAY	Oranges Baked pork and beans. Tomato catsup. Hot corn bread. Bread, butter, coffee.	Bean soup. Saltines. Fried pork chops. Country gravy. Mashed potatoes. Corn on cob. Boiled turnips. Shirred lettuce. Pumpkin pie. Bread and coffee.	Fried beef liver. Onion gravy. Boiled potatoes. Mashed summer squash. Green onions. Watermelon. Bread, butter, tea.

Every week a bill of fare is made out for each meal that is to be served; in the case of holidays a blank is left and a special printed menu is made out. These bills of fare are posted in all branches of the commissary department. Then the cooks, bakers, butchers, and the men in the issue room can make all preparations to furnish all the items listed, and in the exact quantities required.

The number of men to be fed each day varies; men are received and transferred; others go on leave or to the hospital, so that a definite number is never possible to count on for any great length of time. Yet there must be plenty of food without any additional allotment of money. Great care must be exercised or the ration, usually 50 cents per day, will not be sufficient. It is remarkable that such a bill of fare as that for the first three days of a week, reproduced in these columns, can be maintained at that price.

Imagine the great amount of fine detail work necessary to combine the numerous combinations of food in the large quantities required, in order that each man may sit down to his meals on the exact minute, three times each day during the year.

MORE ABOUT PLUTO

By **HENRY NORRIS RUSSELL, Ph. D.**
Chairman of the Department of Astronomy and Director of the Observatory at Princeton University
Research Associate of the Mount Wilson Observatory of the Carnegie Institution of Washington

EVER since the discovery of the new planet Pluto it has been eagerly observed at many places. More than a hundred accurate observations of its place in the heavens have been secured, and from these a rich harvest of knowledge has been reaped. The numerous observations of March, April, and May improved our knowledge of the orbit so much that, figuring backward, its position in past years could be calculated and images of the planet, in some cases very faint, were thus identified on photographs taken at Uccle, Belgium, in 1927, at Yerkes in 1927 and 1921, and at Mount Wilson in 1919. With these available the observed arc of the planet was multiplied twenty fold.

The calculations of Crommelin in England, and of Bower and Whipple in California, based on this fuller material, agree closely and leave no doubt outstanding about the main characteristics of this most interesting object. First and foremost the claim of the newcomer to rank as a planet is decisively confirmed. Though the eccentricity and inclination are greater than for any of the eight principal planets which were previously known, they would pass as moderate among the asteroids and there can be no hesitation in assigning the new body to the ninth place among the sun's more important attendants. There is nothing cometary about it at all; its orbit is far too near a circle and it is eight or ten times as far away as the distance at which even the brightest comets fade out into complete invisibility.

THE early calculations which indicated a highly eccentric orbit turn out to have been upset by a small error—only three seconds of arc—in one of the earliest photographic observations, made with a telescope of comparatively short focus and a long exposure. How such a small departure from exactness may be enormously magnified by the process of calculating an orbit was explained last month. In the second place the orbit, now that we know it, is found to be so similar to that which Lowell predicted from his calculations 15 years ago that it is quite incredible that the agreement can be due to accident. Setting prediction and fact side by side we have the following table of characteristics.

	Predicted	Actual
Period	282 years	249.17
Eccentricity	0.202	0.254
Longitude of perihelion	205°	212°30′
Perihelion passage	1991.2	1989.16
Inclination	about 10°	17°9′
Longitude of node	not predicted	109°22′

Lowell saw in advance that the perturbations of the latitudes of Uranus and Neptune (from which alone the position of the orbit plane of the unknown planet could be calculated) were too small to give a reliable result and contented himself with the prophecy that the inclination, like the eccentricity, would be considerable. For the other four independent elements of the orbit, which are those which Lowell actually undertook to determine by his calculations, the agreement is good in all cases, the greatest discrepancy being in the period, which is notoriously difficult to determine by computations of this sort. In view of Lowell's explicit statement that since the perturbations were small the resulting elements of the orbit could at best be rather rough approximations, the actual accordance is all that could be demanded by a severe critic.

Even so, the table does not tell the whole story. Figure 1 shows the actual and the predicted orbits, the real positions of the planet at intervals from 1781 to 1989, and the positions resulting from Lowell's calculations. It appears at once that the predicted positions of the orbit and of the planet upon it were nearest right during the 19th Century and the early part of the 20th, while at earlier and later dates the errors rapidly increased. Now this (speaking broadly) is just the interval covered by the observations from which the influence of the planet's attraction could be determined and, therefore, the interval in which calculation could find the position of the planet itself with the least uncertainty.

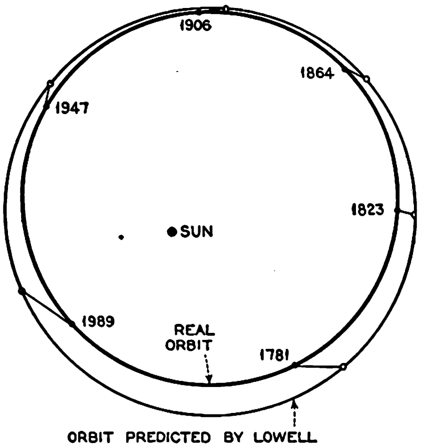


***Figure 1:* Actual and predicted orbits**

In the writer's judgment this test is conclusive. If someone should maintain that a calculation based on wholly insufficient data (and hence physically meaningless) might by some strange bit of luck result in predicting all four of the important elements of the orbit with the relatively small errors shown above, he would still have to account for the fact that the outstanding errors are so *adjusted* that their influences partly counteract one another and bring about the closest agreement of prediction and fact—just at the time when a genuine prediction, based on physically significant data, would have behaved in the same way!

IT may be remembered that substantially the same thing happened in the case of Neptune. Both Leverrier and Adams had assumed that the distance of the unknown planet agreed with Bode's "law," and had therefore taken it much too great. Their calculations made the orbit considerably eccentric (though it is really very nearly circular) but this spurious eccentricity brought the predicted orbit toward the sun in the region where the planet actually lay at the time, and went far to undo the error of two original assumptions. They still had the distance too great, however, and the predicted mass of Neptune was therefore considerably larger than the real value. There were some critics then who maintained that these discrepancies showed that the discovery of Neptune was only "a happy accident" but it has long been acknowledged that these critics were wrong, and the full credit for the great triumph of mathematical analysis has gone where it deserved to go.

History seems this time to have repeated itself closely, except in one tragic detail—Percival Lowell did not live to see his prediction thus fully confirmed. In only one particular was he seriously wrong—he overestimated the apparent brightness of the planet more than ten fold. Several causes probably contributed to this. Pluto is somewhat nearer to Uranus and Neptune than he supposed, hence a small mass would suffice to produce the observed perturbations. Within a year or two—perhaps sooner—someone will doubtless make the necessary calculations and determine the mass of the actual, rather than the predicted, planet. We may guess that it will turn out to be four or five times the earth's mass, instead of six. Even so, it is evident that the planet must be of high density and its surface of surprisingly low reflecting power. But speculation on these matters may well be postponed until observations with the greatest telescopes, under the best conditions of seeing, which will undoubtedly be made this winter, tell us more about the planet's actual diameter.

THE relations between the orbits and motions of the new planet and those of Uranus and Neptune are curious enough to deserve mention. According to Bower and Whipple the mean distance of Pluto from the sun is 39.60 astronomical units (we may note in passing that this is close to the distance predicted by Bode's "law," 38.8, for the next planet beyond Uranus, but we will be wiser if we attempt no explanation). This puts the new planet, on the average, about 900,000,000 miles farther from the sun than Neptune. But the eccentricity is so great that the distance at aphelion is 49.7 and at perihelion 29.55—which is less than the perihelion distance of Neptune (29.82). If the two orbits were in the same plane they would intersect and there would be a chance of a collision. But the high inclination of Pluto's orbit keeps him well out of danger.

Figure 2 shows the orbits, Pluto's being projected on the plane of Neptune's orbit and a little foreshortened, which apparently brings its perihelion farther in. At the points where they appear to cross, Pluto is high above Neptune. The orbits are nearest at point A where the distance is 2.6 astronomical units (240,000,000 miles). This looks considerable, but when compared—as it should be—with the distance from the sun, it turns out to be by far the closest approach among any of the principal planets—when the two planets are nearest their distance from one another is only one twelfth of the average distance from the sun, while at the next closest approach between the earth and Venus this fraction is about three tenths.

Such close approaches are, however, very rare. The period of Neptune is 164.77 years, that of Pluto according to latest calculations is 249.17. (The computers, however, point out that on account of the observational errors this value "is determinate to about a year" and we must not draw conclusions from the last two figures.)

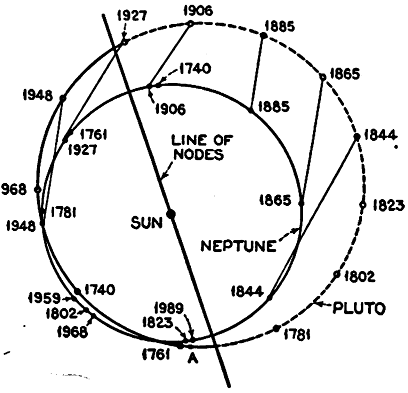

Figure 2: **Neptune's orbit coincides with the plane of the paper, that of Pluto being inclined 17° and intersecting that plane in the "line of nodes." The dotted part is below the paper, the full part above. Thus the orbits are not "grade crossings" and the danger of collision between the bodies vanishes**

Three revolutions of Neptune require 494.3 years. Two of Pluto take 498.3 years. The relative positions of the planets, therefore, almost repeat themselves at intervals of little less than 500 years. Just how they do it can be seen from Figure 2. The positions of Pluto are marked for 12 equidistant intervals, from one perihelion to the next, at intervals of 20.76 years, and also those of Neptune at the same dates. After eight intervals Neptune has completed a circuit of his orbit and advanced a little less than three degrees farther, which explains why the dots representing his positions are arranged in pairs. It appears from the figure that the two planets were nearest in 1892, and that at present Neptune is drawing more and more ahead of Pluto and increasing the distance between them. For more than two centuries the planets will get farther and farther apart, and it will be nearly 500 years before they are as close again as they were recently. "A stern chase is a long chase" and a simple calculation shows that, on the average, Neptune catches up with Pluto once in 486 years, during which interval one planet has made almost three revolutions and the other almost two.

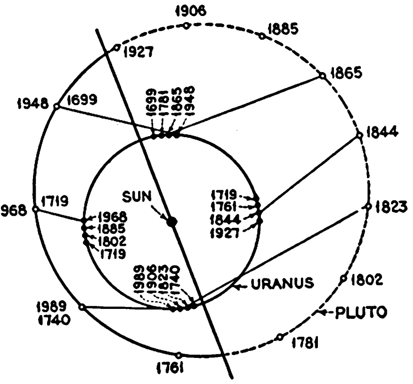

Figure 3: **Relative positions, 1699—1989**

At the recent conjunction, however, the distance of the two planets was 19 astronomical units—more than six times the minimum, and the perturbations, though greater than for centuries past or to come, must have been relatively small. When may we look for a really close conjunction?

A glance at the figure shows that Neptune passed the critical point of its orbit in 1824 and will do so again in 1989, while Pluto reached the corresponding point in 1763 and will do so again in 2012. On the latter occasion Pluto will still have 23 years to go when Neptune reaches the point of approach and, as Figure 2 shows, the planets will be a long way apart. Five centuries earlier Neptune came to the same spot in 1495 and Pluto in 1514, this time only 19 years behind. Working backward in this way we find the conjunctions closer and closer at each interval of five centuries, until in the year 976 B.C. the calculated times for the two planets agree within a few months. Still longer ago Neptune was behind Pluto and the conjunction less close.

IN the future, the successive "returns" of this conjunction will be less and less favorable but, working forward from 1824 when Pluto was 61 years ahead of Neptune and remembering that the former loses four years in every 494, we find that another close conjunction will occur about the year 9238 A.D. Still others will follow at intervals of about 10,200 years.

These figures, however, are liable to alteration if the true period of Pluto turns out to differ somewhat from that here assumed. If, for example, it were one year longer Pluto would fall behind by six years instead of four in three revolutions of Neptune and the dates of close conjunction would be 11 A.D. and 6765 A.D.; while if Pluto's period should be one year shorter the dates would be near 4000 B.C. and 17,000 A.D. and the interval between close conjunctions fully 20,000 years.

In any case it is clear that no conjunctions of the sort will occur until the span of recorded human history is doubled.

When they do happen the planets are close together for half a century or more, as appears again from a study of the figure. Though the orbital velocity of Pluto is on the average considerably less than that of Neptune, it increases so much at perihelion that for a short time the planet of longer period is actually moving faster and the two bodies

Completed derrick on one of the two permits, built as described in the text. The landing wharf, with the steamer *Mahukona* and the tender *Daisy Freeman* in the distance. The derrick barge and the tug *Elwood* may also be seen

OIL FROM BELOW THE OCEAN FLOOR

By C. L. ROBERTS

OIL has been found in burning deserts, waste hills, fever-ridden jungles, cultivated lands where derricks supplant orange groves, and in the frozen steppes of the northland. Under the most favorable conditions drilling for oil is fraught with many difficulties and uncertainties. Consider, then, the problem of sinking a well beneath the ocean bed far from shore; the drilling being attended by legal and physical difficulties which at first glance would appear insurmountable.

The conditions surrounding this latest achievement of oil engineering were tersely described to the contractors, Robinson-Roberts Company of Los Angeles, by the owners of the permit to drill:

"You are to build the foundations for an oil derrick in the Pacific Ocean off shore from the Elwood field, in Santa Barbara County, California. Construction must take care of several things, chiefly prevention of pollution of the ocean by mud, oil, or other waste material; and provision must be made for controlling heavy gas pressure.

"The beach bordering our lease is backed by precipitous cliffs 200 feet or more in height and is so narrow that it is completely submerged at high tide. All shore land above the high-tide line is controlled by our opposition who are patrolling it with armed guards with orders to arrest trespassers.

"Last, but not least, you have just three months to complete the contract and 'spud in' the well or we will lose our permit."

Investigation disclosed that under a recent California law, drilling permits were being granted on state-controlled tide lands along the coast line. Preference was given to littoral owners but through a slip of some sort the permit in this instance had been given to a company that did not have shore lands and wells in this vicinity. The littoral owners sought to block the permitees and keep them from drilling within the time limit specified, hoping thus to compel the permit to lapse, when they would be in a position to apply for a new drilling right themselves.

THE prize at stake was an untold amount of high gravity oil, the type of crude which is the life blood of the industry. It has a high gasoline content and its discovery always is followed by a stampede.

Faced with this problem the contractors were required to pioneer, using methods of construction never tried before, and meeting conditions, the effect of which could not be foretold. Illustrative of this was the first question presented—that of wharf construction leading from the beach to the site of the derrick foundations. It was discovered that the ocean floor was a shale bed with no sand covering. This eliminated the possibility of using round wooden piling, but something had to be found that could be driven into this foundation and still have the structural qualities of the wooden piling.

Decision fell on steel, and what is known as the "H" column was selected. This type of piling has since been found to have the double virtue of being able to penetrate the shale and to resist by sheer weight the flotation action of the ocean.

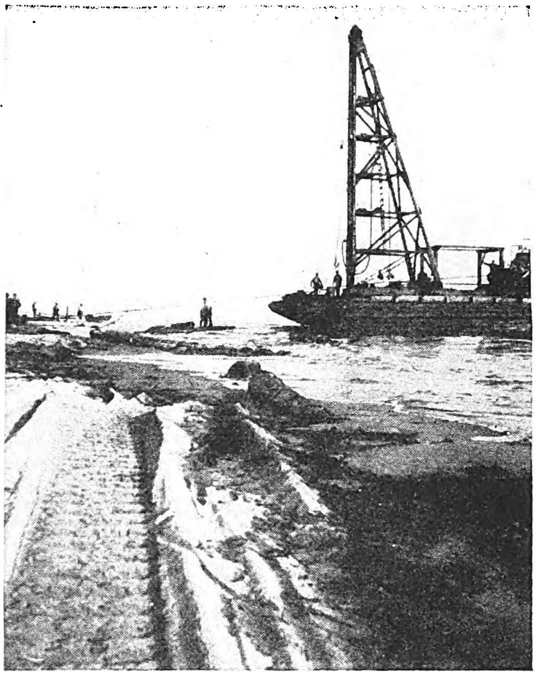
The anchoring of the derrick, which on land is done with guy wires, was the next problem. It was solved by designing a foundation consisting of five concrete-filled cofferdams. Four of these were placed at the corners of a square and upon these the legs of the derrick were to rest. The fifth, larger than the others, was in the center and was to support the drilling machinery. Here also the question of pollution was disposed of. Under the permit any fouling of the ocean waters meant the loss of drilling rights. This central cofferdam was hollowed out and a steel diaphragm connecting with the four foundations was so constructed hat it sloped toward the center, thus catching oil drippings from the machinery, mud from the well, and things of like nature.

However, the two greatest problems were yet to be solved. The first meant working out new methods of construction where all contact with shore was cut off; and the second, obtaining an adequate supply of water for machinery and men.

Purchase of the steamer *Mahukona*, a wartime vessel, and her outfitting to carry supplies enough for the job and to house the workers, was decided upon as the answer to the first of these questions. On June 5 the steamer was placed in drydock in San Francisco and 10 days later she dropped anchor off Elwood. In the meantime she had been converted into a floating hotel and warehouse. Every available space was utilized, and a boat with quarters for a normal crew of 25 now housed 150 men, while every article necessary to the construction of wharf and derrick was stored aboard.

A WORD as to life on that ship will be apropos here, as it is indicative of the difficulties encountered. Anchored within sight of shore, its passengers were unable to set foot on land for diversion or entertainment. Every man was keyed up to high tension, working against time in the effort to complete the contract successfully. Three shifts of men ate, slept, and took their leisure hours in this restricted area so that one man's breakfast was another's lunch and the third's dinner. Men were sleeping, lounging about, or working, according to their employment hours. Beds were made and slept in, only to be remade immediately to make way for the next crew of sleepers. Meals were prepared in a galley eight feet by eight feet and the stove never got cold, for as soon as one meal had been served, the cook began preparation of the next.

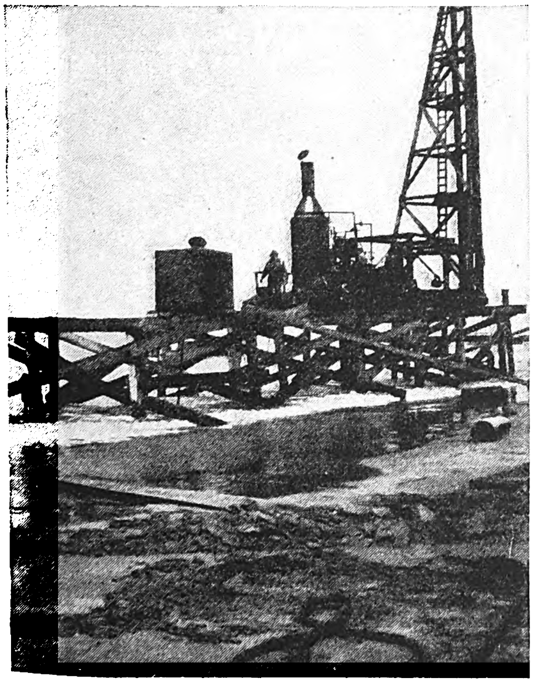
With anchorage moorings prepared for the steamer, a derrick barge, two lighters, and two small launches, the actual work of attacking the first construction began. It was determined to build a small wharf on the beach to keep the machinery above high water. A load of short steel piles was sent ashore, through the surf in a skiff. Then the fun began, for it was some time before it was found that, to row a boat ashore through the breakers, we had to turn around and back her in. To this maneuver, sea authorities do not agree, even such a one as Richard H. Dana in his "Two Years Before the Mast," but it proved correct for us. It took several upsets before the lesson was learned but after that we always kept the bow seaward and thus escaped wettings.



Beaching the barge which carried the pile driver. Her hoisting engine pulled her in

THE short steel beams were placed upright in the sand by hand and a platform rigged on these posts. A water tank was floated ashore and rolled up on the small wharf. Then the barge came in with water tanks aboard and a man was sent through the surf with a hose-line, and a supply of fresh water was pumped into the big tank. Oil drums were floated in, salvaged on the beach, and rolled up onto the platform. Next a Caterpillar tractor, equipped with a winch, was sent along the beach at low tide, walked onto the wharf, and the shore start had been made.

It was necessary to get a pile driver on shore to begin constructing the permanent pier. A driver had been built on one of the barges by use of the derrick-barge and ships' gear. It was found that low tides occurred at night and highwater at noon. The plan was to beach this barge at high tide, and float it again at some subsequent high tide. Such a procedure would be risky due to the nature of the ocean bed which was cut up with finlike reefs. To strike one of these would mean days of costly delay.



The pile driver on falsework in the surf after it was landed from the beached barge, ready to begin work

An anchor was run ashore and sunk in the beach. This was attached to the bow of the barge to hold her on her course, while port and starboard anchors, which had been placed a short distance from shore, were attached to her stern, their lines run to the drums of the driver's hoisting engine. A stern anchor held the aft end in line. With the engine started, the forward line was taken in and the aft lines paid out, thus hauling the barge onto the beach through the surf.

Once grounded, all lines were made fast. Then a wire cable was attached to the driver and run to the winch of the tractor. The tautness of this cable minimized the surging back and forth in the surf.

WITH carbide flares providing light for night work, with no rest for the men, and with every available hand on the job, a race began to get sufficient piling driven so that the driver could be pulled clear of the barge before the next high tide. Men worked in water to their waists. Any tools that were dropped were left as there was no such thing as groping about in the sea to recover lost articles. Hours of high speed work passed with no thought of rest, but the next high tide saw the pile-driver pulled clear and the barge re-floated. The first real battle had been won.

The abnormally high tide that had favored work with the barge and driver, brought disaster to the temporary wharf, which collapsed, throwing the fresh-water tank into the sea. The water was so polluted with salt that it could not be used in the boilers and thus the problem of fresh water became acute.

Water consumption for men, ship,

and job was about 25 tons a day. The capacity of the *Mahukona* was 500 tons, of which 375 were in the "wing tanks," triangular in shape and running fore and aft along both sides of the vessel. Unless the ship were heavily loaded, these could not be filled, or the boat would capsize. The nearest water supply was at San Pedro, 125 miles away with a cost of 300 dollars for a tow from that port. In addition the only water-barge available had a capacity of 90 tons which meant a towing expenditure every third or fourth day. The solution came with the chartering of the steamer *Daisy Freeman* which was used as a water carrier and for lumber storage.

ALL did not run smoothly on the job. What with water, tides, fog, crowded quarters, foaming boilers, and loss of carbide flares and tools overboard, there were plenty of problems that had to be met as they came up. The gasoline launch began slipping its clutch owing to the propeller being fouled in the kelp. A tug was chartered to replace it. This boat was caught in a surge, its tailshaft was twisted off, and it went ashore. The barge used to beach the first driver, and later used for a second driver which began work on another permit covered by the drilling operations, got adrift and struck a reef. Here was a tug ashore and a barge hung up on a reef. Troubles never came singly but seemed to pile up all at once.

The tug was pulled off but this left us with men ashore and no means of conveyance to the mother ship. A fishing boat, skippered by an Italian who could not understand English, was hired, thus affording temporary relief, but the menace of the barge remained.

Far out beyond low tide level—one of the completed oil derricks

Derelicts have a way of wandering at inopportune times and there was the danger that the barge would suddenly float and go crashing through the falsework, which would be such a serious setback in time that the contract would be lost. And float it did, at 3 o'clock one morning. Luckily, it cleared the workings and was blown up by dynamite to prevent it from endangering our construction work further.

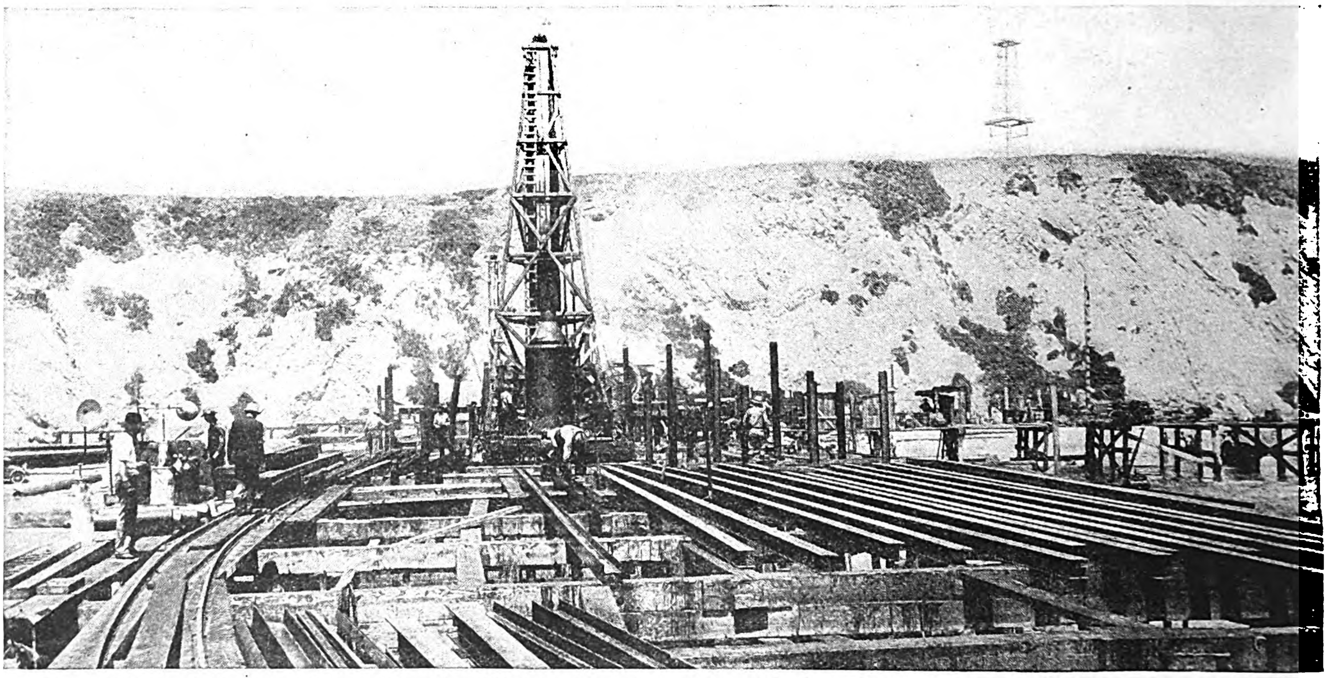
With work well started on the second permit, both jobs swung along at a good clip. Most of the material used was floated ashore and for over a month there was not a man on the job who was not wet from head to foot every hour of the working day. The genial steward, asking one of the men if there was anything dry on him, received the laconic answer: "Yeah, my hat." Yet, despite such handicaps, we progressed.

WITH the falsework driven seaward to the end of the dock, the pile driver headed ashore and took up the work of driving steel piling. The derrick barge was brought into play, being anchored in the surf. Her 100-foot boom swung load after load from the barge to the wharf and despite the lifting of the surf, which increased the arc of the boom, only one sling-load was lost overboard.

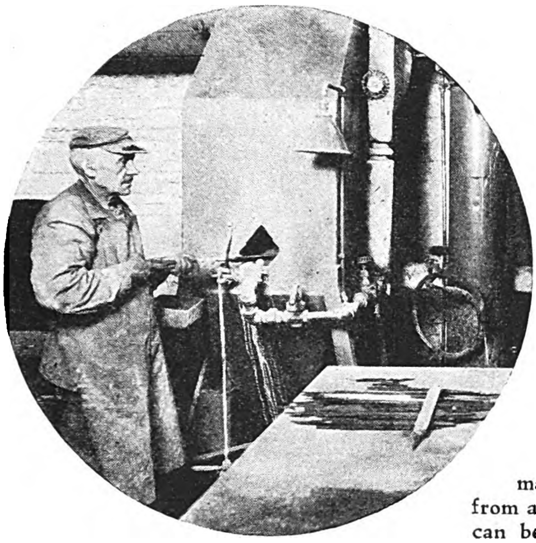
By this time divers were employed to retrieve tools and materials that might fall from the wharf or from the cofferdams where the work of erecting the steel derrick was under way.

It was on August 10, less than two months from the time the *Mahukona* had set sail from San Francisco, that the first dock was ready, derrick erected and everything prepared for the spudding in. The second dock was completed 10 days later. The labor and effort this cost and the trying conditions under which it was accomplished beggar description. The joint cost was approximately 400,000 dollars.

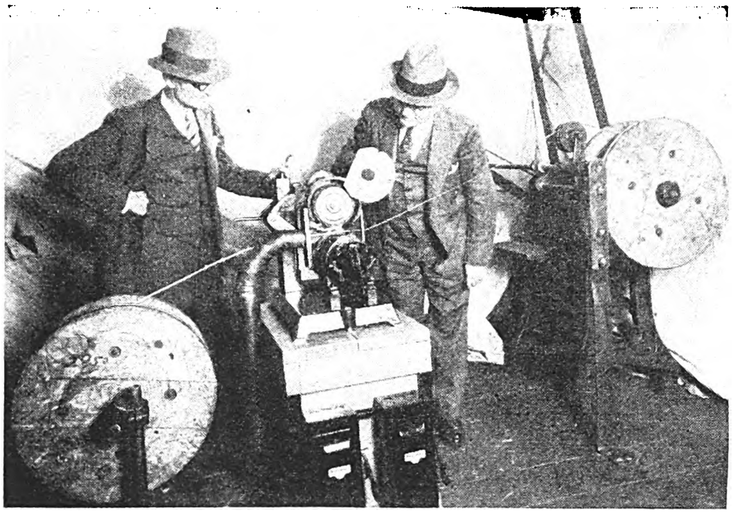
Achievement brought a two-fold satisfaction. Pioneering methods in oil drilling had proved successful, obstacles that seemed insurmountable had been overcome, and oil in good flow was struck without further trouble.



One of the steel wharves under construction. Heavy steel and timber work were necessary. This view shows the character of the cliffs above the work and a producing well on the mesa above the beach. The pile driver is driving the "H" beams



Reclaiming used files by the steam sand-blast method. Approximately 15,000 files a month are reclaimed at the East Pittsburgh plant alone



Above: A cable skinning machine removing the covering from a copper cable so that the metal can be used over again. Formerly, damaged wire became worthless scrap

Used carbon paper can be rejuvenated three or four times by passing over an electrically heated cylinder. The saving is worth while

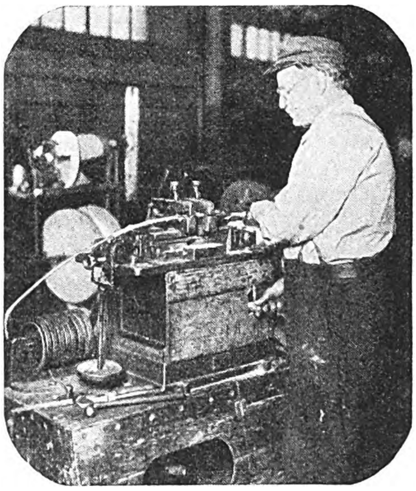
WASTE

The portable exhibit is shown all over the plants and is one of many such presentations carried around on trucks

Feet can be welded on discarded calcium carbide containers and so make perfectly good waste cans for the shops. Why buy new waste cans?



Right: Short ends of material make a real waste problem. This electrical butt-welding set makes "big ones out of little ones." The scrap pile is cut down still more

FACTORY WASTES TURNED TO PROFITS

INDUSTRIALISTS have long been worried by two problems which are always present. One is safety and the other is waste. Some of the factory wastes are unavoidable, but there are others that a little care will prevent, particularly with commonplace items which are often overlooked on account of their apparent insignificance. Competition, especially in the form of foreign made goods produced by cheap labor, is steadily becoming keener and if we want to hold our premier position by producing, as we have done in the past, at costs that will allow us to compete, we must eliminate the demon waste. Manufacturers are co-operating with the great engineering societies to bring this home to the employees by posters, actual examples of waste, and by a clever system of rewards for suggestions. The results of the campaign for waste prevention are far-reaching. The Oakland Motor Car Company saved 542,000 dollars in about a year as a result of suggestions. We illustrate some of the things done at the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pennsylvania.

SCATTERED LIGHT AND THE RAMAN EFFECT

By **R. W. WOOD, LL.D.**
Foreign Member of the Royal Society
Professor of Experimental Physics at Johns Hopkins University
Contributing Editor, *Scientific American*

IF we are sitting in a darkened room and a beam of sunlight filters in through a chink in the shutters, it is a matter of common observation that the beam is itself invisible from the side, unless there is smoke or fine dust particles in the air. But when a whistle blast enters a room through a hole in the wall, the waves spread out, filling the entire room uniformly, and the ear hears the sound in one place as well as in another. We may explain this action of sound by considering the vibrating air, in the aperture in the wall, as itself a source of sound, which sends out waves uniformly in all directions.

This difference in the behavior of light and sound we express by saying that light is propagated rectilinearly or in straight lines, while sound is not, and it was precisely this difference in behavior that was raised as an objection to the wave theory of light when it was first stated in definite form by Huygens in 1678. The difficulty was cleared up by Fresnel who proved mathematically that, in the case of the extremely short waves of light, rectilinear propagation and the formation of shadows were due to interference. In other words we may consider that secondary waves of light start out laterally from every point on the beam of sunlight, just as we considered the sound as radiating from the aperture, but if we calculate their combined effects at any point outside of the beam, the resultant is zero, or complete darkness.

WE need not go into the proof of this, but it can be shown mathematically that, at all points within the shadow, radiations from any point in the illuminated region are destroyed by other radiations from some other point, the two sets of disturbances arriving half a wavelength apart and destroying each other. This is known as the Fresnel-Huygens principle.

Very high pitched sounds behave somewhat like light, evidence of "shadows" frequently being observed, while in the case of the very high frequency waves from vibrating quartz plates, such as were employed by Langevin for submarine signaling (see article "Sounds that Burn," SCIENTIFIC AMERICAN, March 1928) the "sound" can be projected through the water to a great distance, like the beam of a search light. Here the Fresnel-Huygens principle operates to destroy the spread in lateral directions. If any material particles, such as minute specks of dust, are suspended in the air traversed by the beam of light, each particle scatters light into the shadow, and if very small indeed, the particles scatter blue light more powerfully than red or yellow. In other words the light diverted into the region of shadow is rich in radiation at the short wavelength end of the spectrum. The selective scattering of blue light can be seen by holding a lighted cigarette or cigar in a beam of sunlight, and viewing the smoke against a dark background. In general there will be several filaments of smoke rising, some white, in which the particles are comparatively large, and some blue in which they are smaller.

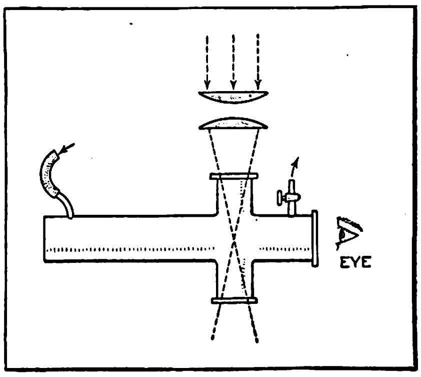


Figure 1

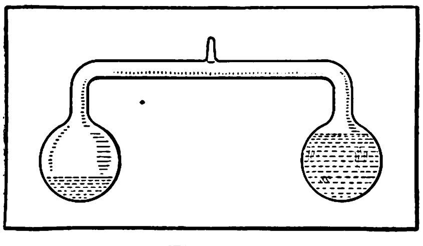

Figure 2

The blue color of the sky was formerly thought to be due to a similar scattering of light by very small dust particles suspended in the air of the upper atmosphere, but Lord Rayleigh's calculations indicated that the scattering in this case was due to the actual molecules of air. Many years elapsed before this scattering of light by pure dust-free gases was detected in the laboratory by Lord Rayleigh's son (the present Lord Rayleigh) and independently and at about the same time by Cabannes, a French physicist. Sunlight was focused by a lens at the center of a black tube, through a window in the wall, and a very blue cone of luminosity was observed through a glass window in the end of the tube, which was filled with air filtered through cotton-wool to remove dust particles. (Figure 1).

SIMILAR results were obtained with other pure gases, even with hydrogen, the scattering power of which was many times less than that of air, while that of ether vapor was much greater. Some experiments were made by the writer at East Hampton, New York, with a view of comparing the intensity of the light of the blue sky with the intensity scattered in the laboratory by dust-free air. Sunlight was concentrated by a "reading-glass" lens six inches in diameter, at the center of a black tube, similar to that of Lord Rayleigh, and the blue cone seen in the tube was matched against a bit of blue sky reflected in a small mirror of black glass, which reflects 4 percent, through a very narrow slit in the rim of a large disk of black cardboard, rotating at high velocity in a dark room. In this way the intensity of the sky light was reduced to that shown in the tube. The total amount of air directly above us is the equivalent of an ocean of air of uniform density at atmospheric pressure five miles deep. This thickness of air, illuminated by normal sunlight, forms the blue sky. In the laboratory the layer illuminated was less than one eighth of an inch in thickness but the illumination at the focus of the lens was about 1400 times that of normal sunlight. The two could be matched by making the slit in the disk sufficiently narrow, and calculations showed that the blue sky could be fully accounted for by molecular scattering of light by the air.

A similar scattering was observed in pure distilled water, freed from suspended motes by repeated distillation *in vacuo* without ebulition in a double bulb, as shown in Figure 2. The bulb containing the liquid should be heated to only 15 or 20 degrees above room temperature, or one bulb may be immersed in ice and the other kept at room temperature. After about one quarter of the liquid has passed over, this is shaken about in the bulb and then poured back into the other bulb, carrying with it any motes which may have adhered to the walls. After two or three repetitions of this process, nearly the whole of the liquid is distilled over, and it will now be found to be "optically clean"; that is, it will show no bright specks when sunlight is focused at the center, but only the pale blue cone of light scattered by the water molecules. It must be viewed against a black background.

NOW a very striking thing is shown in the case of scattering by a liquid and its vapor. We might very reasonably expect the scattering of the light to be proportional to the number of molecules present, and as there are roughly 1000 times as many molecules in a given volume of liquid as in an equal volume of its vapor at atmospheric pressure, we might look for an intensity 1000 times as great in the liquid as in the vapor. As a matter of fact we observe an intensity less than 50 times that of the vapor.

This is, however, precisely in accord with the theory, for in the liquid we have a nearer approach to a continuous medium and if the medium were perfectly continuous and structureless there could be no scattering, for in this case the secondary waves would destroy each other, just as they do when no material medium at all is present and they originate in the vibrating "ether," the hypothetical "medium," the vibrations of which constitute light.

This means that, in the case of the liquid, "interference" is taking place between the scattered radiations, and the lateral diffusion of light by the molecules is partially prevented. Transparent crystals, such as quartz, scatter still less light since the molecules are arranged in a perfectly regular manner on a so-called "lattice," and this condition approaches the condition of a continuous medium from a mathematical standpoint; at all events there are no variations in density from point to point such as occur in a liquid as a result of thermic agitation or the to-and-fro oscillation of the molecules which constitutes heat.

The absence of scattering in the case of a crystal lattice can be beautifully shown with a thin flake of mica. Both surfaces should be freshly cleaved, which can be most easily accomplished by rubbing the edge of a thin plate with the side of a needle until it is flattened, and then inserting the point between the layers of the mica. If a flake prepared in this way is attached to the edge of a carefully cleaned cover-glass, such as is used for microscope slides, the strong scattering of the glass, as contrasted with the absence of scattering by the mica, can be shown by focusing sunlight first on one plate and then on the other, viewing them against a dark background. It was formerly supposed that no change of color was produced by the scattering; or, speaking more accurately, no change of wavelength in the case of the blue smoke or blue sky. There is an apparent change of color, to be sure, but the scattered blue light was originally present in the white light, and the color is not produced by a change in the length of the light waves.

In 1923 Smeckal predicted from the modern quantum theory of light that if a medium was powerfully illuminated with monochromatic light—that is, light of a single wavelength, analogous to a pure musical tone—there should be present in the scattered light, faint traces of other monochromatic radiations and that a "spectrum" would be characteristic of the substance illuminated.

FIVE years elapsed before this prediction was verified by Sir C. V. Raman, the distinguished Indian physicist of the University of Calcutta; and at very nearly the same time by Landsberg and Mandelstamm, the former working with various liquids, and the latter with crystalline quartz.

The arrangement used by Raman is shown in Figure 3. The light from a horizontal mercury arc-lamp (through a draftsman's error, a carbon arc is shown) was focused at the center of a spherical flask filled with benzene or any other liquid, and the spectroscope pointed at the illuminated region at the focus. Exposures of many hours were necessary to secure a photograph of the spectrum, owing to the faintness of the light. Numerous bright lines were found in the case of every liquid examined. In the majority of cases the new lines were of longer wavelength than that of the exciting light—that is, they were on the red side of the spectrum lines of the mercury arc, but in the case of some liquids, such as carbon tetrachloride and chloroform, lines of shorter wavelength were found on the violet side of the same lines.

At first sight it might appear as if this was merely a case of fluorescence, but Raman found a remarkable relation between the wavelengths of the new lines and that of the exciting radiation, which is quite different from anything observed in the case of the phenomenon of fluorescence.

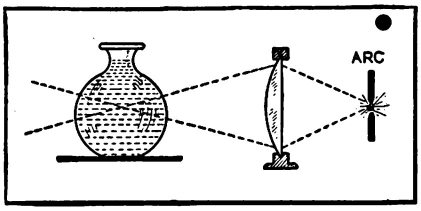

Figure 3

In the first place he found that the arrangement of the spectrum lines in the groups excited by the various mercury radiations was exactly similar. For example, carbon tetrachloride gives a spectrum shown by diagram in Figure 4, the two mercury lines being indicated by arrows. The lines to the left of the mercury lines are of shorter wavelength than that of the exciting line and are called "anti-Stokes lines," being exceptions to a supposed law formulated by Sir George Stokes, that, in the case of fluorescence, only radiations of wavelength longer than that of the exciting light could be emitted. The relative spacing is the same to the right and left of the exciting mercury line except that it is reversed. Secondly, he found a very remarkable relation between these new lines and the absorption bands of the substances in the remote infra-red region of the spectrum. If the frequencies of vibration of the Raman lines are subtracted from the frequency of the exciting light the numbers obtained represent the frequencies of the infra-red absorption bands which are found experimentally only with considerable difficulty.

WE thus have a very simple and direct method of investigating the infra-red absorption of substances by means of visible light, and of securing data on the structure of complex molecules. The matter has turned out to be somewhat more complicated than was at first supposed, for not all Raman lines have infra-red absorption bands associated with them, and some infra-red bands are not represented by Raman lines, but the theory is being gradually worked out.

The original and simpler theory, as first given by Raman, explaining the formation of anti-Stokes lines, is as follows: The quantum theory of light regards a beam of monochromatic light, say the green light of the mercury arc,

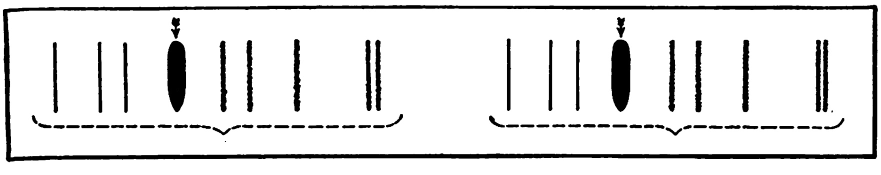

Figure 4

as made up of discreet "packets" of energy, all of the same magnitude, called "light quanta." As the beam diverges in space these quanta merely get farther apart, without suffering any loss of energy. The energy content of a light quantum increases progressively as we pass from the red to the violet and ultra-violet.

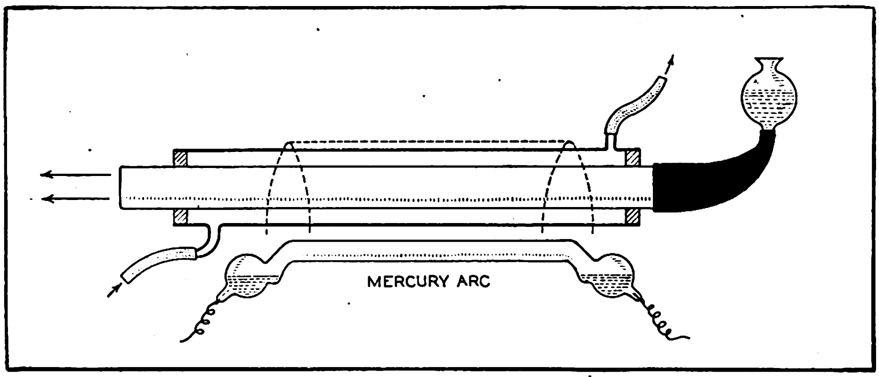

Figure 5

When now one of these quanta enters the benzene, one of three things may happen. It may be diverted from its original direction without loss of energy, giving the line of unmodified wavelength in the Raman spectrum. It may give up some of its energy to a benzene molecule, and emerge from the medium with diminished energy, giving a line on the red side of the exciting line. Or it may abstract a certain definite amount of energy from a molecule already in an excited state—that is, in vibration as a result of temperature—and emerge with increased energy, giving an anti-Stokes line. It is found that the intensity of these anti-Stokes lines increases as the temperature of the medium is raised, as more molecules are then in excited states.

The method of illumination employed by Raman is very inefficient as only a small percentage of the light of the lamp is utilized. The arrangement now universally used is the one described by the writer shortly after Raman's first publication; the liquid under investigation is contained in a glass tube provided at one end with a window of glass fused to the tube, or with a flattened bulb, the other end being drawn off obliquely and painted black. This tube may be surrounded with a second tube in which water circulates to prevent overheating, and the arc is brought up as close to the tube as possible, as shown in the drawing above (Figure 5).

A HALF cylinder of polished aluminum placed over the tubes still further augments the illumination. The scattered light is photographed with a spectroscope pointed down the tube toward the black cone at the farther end. A still further improvement is to use a large glass tube filled with an absorbing liquid which cuts out the light of all but one of the mercury lines, and, acting as a cylindrical lens at the same time, focuses the light on the tube containing the liquid. In this way it is possible to photograph the stronger Raman lines in a few minutes.

A helium "vapor lamp" has also been used by the writer for the excitation of Raman spectra. With a special filter, consisting of a tube of glass colored black with nickel oxide, which surrounded a tube filled with benzene, both being mounted beside the arc and completely surrounded by a cylinder of highly polished sheet aluminum, the Raman spectrum excited by the strong ultra-violet helium line 3888 was obtained.

Three spectra of benzene are reproduced in Figure 6, the upper two by the mercury, and the lower by the helium, arc. They are reproduced as "negatives"; that is, the bright spectrum lines come out dark. The upper one was made with the mercury arc light filtered through a tube containing a saturated solution of a salt of praseodynium, which absorbs the continuous spectrum of the arc in the region where the Raman lines appear and permits the fainter lines to record themselves. The excitation in this case is by the triple mercury line 4358 at the left, and also by 4046 and 4077, which lie still farther to the left and do not appear. The black area at the extreme left is the (over exposed) image of the light of the 4358 triple line scattered without change of wavelength with an intensity of about 500 times that of the strongest Raman line. Lines numbered 1 to 6 inclusive, are excited by 4358, and lines *a* and *b* by 4046 and 4077, *a* and *b* being the same Raman line as 6 by the other excitation. The two lines to the left of 3 are identical with 3, being excited by the two faint companions of 4358, shown as double arrows above the spectrum. Two other fainter mercury lines show to the left of 6. Line 5 is double.

The middle spectrum was made with a quinine filter, which absorbed 4046-4077, and lines *a* and *b* are absent.

The lower spectrum was taken with helium excitation, and is the simplest of the three, as the exciting line 3888 is single. Two faint helium lines have been marked out by covering over on the print.

These are probably the best Raman spectrum photographs that have been made up to the present. Raman spectra have also been made of gases at atmospheric pressure by Rasetti, the writer, and others.

THE first gas studied was hydrochloric acid, contained in a large glass tube about six feet in length mounted in contact with a Cooper Hewitt mercury arc of the same dimensions, the two being surrounded by a hollow cylinder of polished aluminum. The light of the arc, imprisoned by this reflector, was beaten back and forth through the gas tube, securing the maximum intensity of illumination. The spectroscope was pointed so as to "look down" the entire length of the gas tube through a bulb of thin glass blown on the end. With an exposure of only 24 hours a strong Raman line was obtained which was shown by calculation to be associated with the infra-red absorption band of the gas, previously discovered, while the exciting mercury line, scattered without change of wavelength, was bordered on each side by regularly spaced lines which can be shown to be the result of rotation of the hydrochloric acid molecules.

This very important discovery by Professor Raman is opening up a wide field of investigation and throwing new light upon the theory of molecular structure.

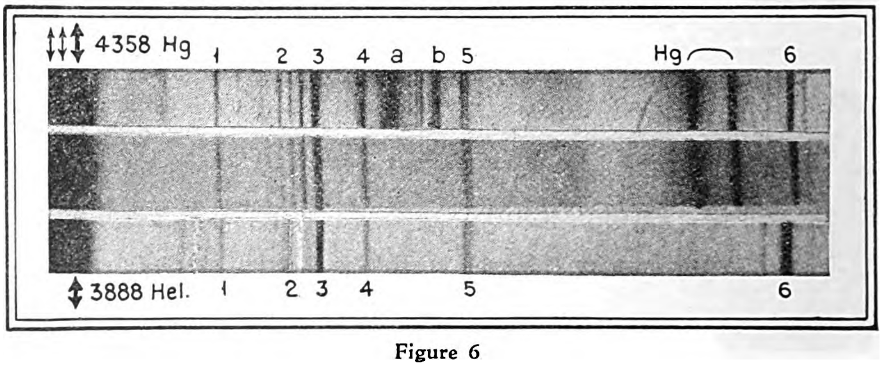

Figure 6

AN ATOM OF LUTECIUM

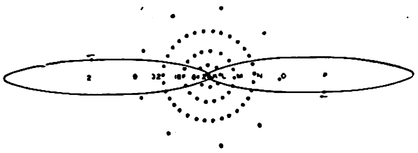
By NELL RAY CLARKE

FOR the first time the atomic structure of an atom of lutecium has been plotted, this having been accomplished by Dr. William F. Meggers of the Bureau of Standards. The arrangement of the electrons in an atom of lutecium as plotted by Dr. Meggers suggests the nose and wings of an airplane with a radial engine. To Dr. Meggers the arrangement of dots mathematically spaced gave a great deal of satisfaction. He said, "The thrill and satisfaction derived from this discovery may be compared with that accompanying the discovery of the ninth planet of our solar system. Indeed, the lutecium atom is pictured as a solar system with a nucleus, corresponding to the sun, surrounded by electrons which correspond to the planets. However, instead of merely nine major planets which are known to belong to the solar system, the lutecium atom has 71 planetary electrons."

FOR years Dr. Meggers has been working over the riddle presented by the group of elements known as the "rare earths," about which little or nothing is known. The mere names of these elements present for the layman as well as the scientist, perhaps, the most formidable array of unpronounceable words to be found in the English language. Try them out on yourself, if you don't believe it. Here they are—cerium, praesodymium, neodymium, illinium, samarium, europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, and lutecium.

It is only within comparatively recent years that these elements have been isolated; lutecium was isolated in 1907 by the French chemist Urbain. They are for the most part very rare, and although a few of the more common ones have found commercial uses, the rest may be regarded at present as interesting chemical curiosities. They form a unique series of elements, with chemical and physical properties so closely similar that it is exceedingly difficult and laborious to separate them from one another.

A few years ago, the Bureau of Standards purchased for experimental purposes a tiny tube of lutecium oxide from the Welsbach Laboratories in Vienna, almost the only place in the world where it is available. Up to that time, no one had ever worked out the structure of the atoms of a single one of these rare earths. But Dr. Meggers decided to try it, following the lines of the Bohr theory. This had often been attempted before, but Dr. Meggers and his assistant, Mr. Bourbon Scribner, are the first to succeed.



Bohr model of lutecium atom. Orbits of two of the 71 electrons are shown. Diameter of atom is approximately one 50,000,000 inch

According to Bohr's theory, the atoms, or smallest units of the different chemical elements, are conceived as being built up of positive and negative units of electrical charge, called protons and electrons, respectively. Beginning with hydrogen, which consists of one proton and one electron, the successive addition of protons and electrons explains the structure of heavier and more complex atoms, until the end of the list is reached with uranium which has 92 outer electrons.

First Dr. Meggers had to get the spectrum of lutecium. To do this he impaled some of the lutecium oxide on a piece of wire and passed a current of 220 volts through it to get the spectrum of the neutral atoms. Then by exciting the spark to 40,000 volts he was able to remove one of the electrons from the atom, which gave the lines of the spectrum from the atoms of lutecium with one electron off. Later he got the lines of lutecium with two electrons off; these are in the ultra-violet end of the spectrum and therefore are not visible to the eye though they affect a photographic plate as does visible light.

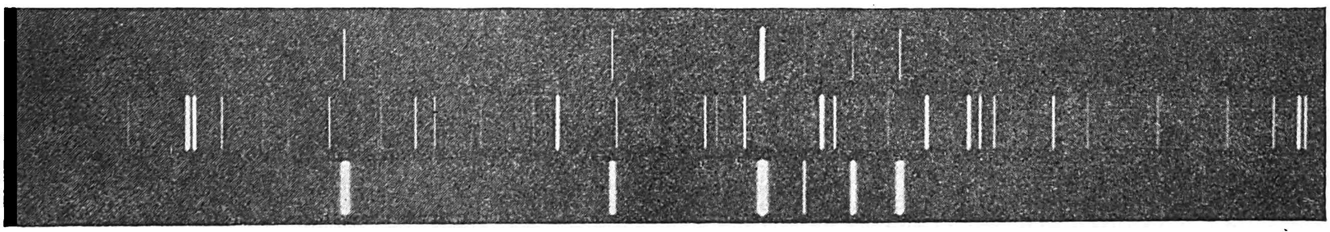
He found that there are 200 lines in the spectrum of neutral lutecium and 450 lines in the spectrum of lutecium atoms lacking one electron. The illustration shows only a few inches of the spectrum; the whole spectrum measures from eight to ten feet in length. The position of each of the lines relative to known wave-lengths in the iron spectrum was measured—a task almost incomprehensible to the layman because of the infinite pains it required.

THE results of the calculations which revealed the regularities among spectrum lines and disclosed the structure of the atom he set down in tiny figures arranged in neat rows. There were enough of them to cover a sheet of paper as large as two card table tops. The graphs he drew to illustrate and explain his work are more complicated than the geometrical designs President Hoover draws during his interviews or while telephoning.

By studying these results Dr. Meggers obtained the solution of the problem of just the exact position of each electron in the atom of lutecium. He is now working upon calculations which will enable him to plot the atomic structure of some of the other rare earths. The spectra of ytterbium, the one being studied at the present time, will be more complicated than those of lutecium, but the atomic structure will be some integral part of the atomic structure of lutecium.

◆

A Mexican savant believes he has succeeded in creating living substance, protoplasm, from chemicals. In an early number an account of his intriguing experiments will be described.
—The Editor.



A portion of the spectrum of lutecium. The top spectrum is of the neutral atoms; the middle one is an iron spectrum ("comparison spectrum"); and the bottom is the spectrum of lutecium with one of the planetary electrons removed

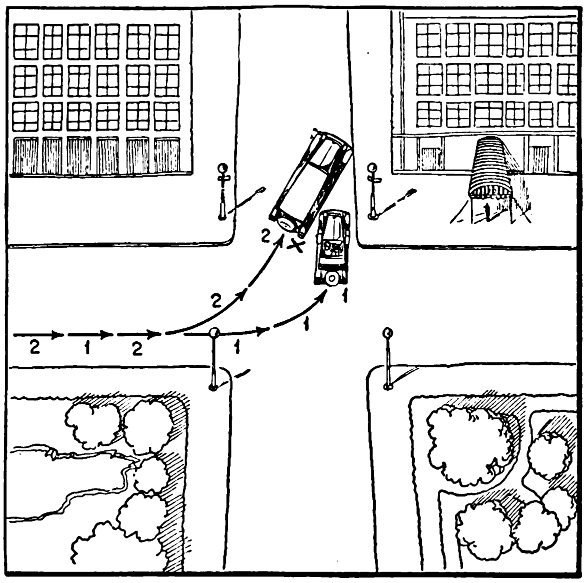
SCIENTIFIC CRIMINOLOGY—
THE PISTOL WITNESS

As a fitting sequel to his article in our October issue, Mr. Gorman has set forth in these pages an actual case taken from the New York police records, in which it is shown how the study of firearms and ammunition is applied in every-day police work. He makes no pretense of telling a mystery story; he gives a bald statement of fact.—*The Editor.*

By STANLEY F. GORMAN

Lecturer on Bullet and Firearm Identification,
Police College, City of New York

With the roar of hard pressed engines, a heavy sedan and a powerful coupé whirled around the corner racing side by side. The sedan suddenly spurted ahead and swung diagonally across in front of the coupé. With a screeching of brakes a collision was avoided and the two cars stopped close to the curb. From the coupé, now in the rear, leaped a man with a gun in his hand. The left-hand door of the sedan opened and a second man, also with a gun in his hand, stepped forth. Shots were fired and a man was seen to leap back into the coupé, back away from the sedan, and speed away from the scene.



Scene of the deed. The cars are shown in their relative positions at the time of the fatal shooting

The exact details of what occurred at this recent homicide in New York were beclouded by different versions rendered by different witnesses. According to some, the man in the sedan started to get out the left-hand door, hesitated, and then got out the right side. Others say that he emerged from the left-hand door. In any event, when the police arrived on the scene, the driver of the sedan was found crumpled in a heap directly behind the right-hand rear wheel of his car. It then remained for the police and detectives to make a thorough examination of the scene and from the facts obtainable from witnesses and clues, deduce the facts and bring the murderer to justice.

When the detective arrived on the scene of the crime he found that the driver of the sedan had been removed to the hospital as he was still alive and there were possibilities of saving his life. It developed, however, that shortly after entering the hospital he died. There was a group of about a hundred people surrounding the sedan and held back by the police in charge of a sergeant. The detective found upon questioning the police that the pistol which had been dropped by the driver of the sedan when he was wounded had been carefully picked up by the sergeant. This was done with a pair of pliers in order not to destroy any possible fingerprints. The weapon was placed on the floor of the sedan in the rear compartment so that it would be undisturbed until it could be examined.

Upon examining the gun, which was a 32-caliber automatic pistol, the detective noted that the safety catch was off the safe position, indicating that its carrier had it in readiness for use. With a screw driver the detective pushed the catch to the safe position and picked up the pistol, handling it by means of the screw driver placed through the trigger guard. He then examined it as carefully as possible under the circumstances and looked into the muzzle for powder smudges. He also smelled it for the odor of powder in an endeavor to determine whether or not the gun had recently been fired. It must be remembered that he could not determine whether or not the gun was loaded as this had to be done after the search for fingerprints was made; handling might destroy fingerprints which could be used as evidence. As far as the detective could determine, the weapon had not been discharged, for the barrel contained neither powder smudge nor discoloration and had no burned-powder odor. Furthermore, it was apparently quite wet with oil.

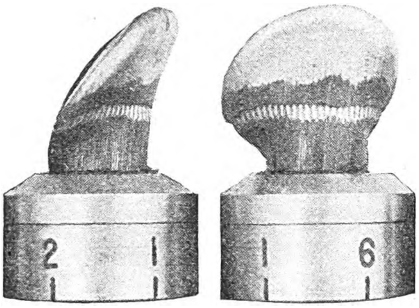
The firearm was then handed to the fingerprint expert who dusted one side carefully with white clay powder and examined the surface. The gun was then turned over and the other side dusted but no fingerprints were found that were distinct enough to be classified. This frequently is the case with pistols because of the difficulty of obtaining a distinct fingerprint on the checked surface of the grip. After the fingerprint examination it was possible to determine whether or not the pistol was loaded. The magazine was found to contain five 32-caliber cartridges, and a sixth cartridge was in the chamber. These cartridges, as well as the interior of the weapon, were covered with oil and an examination of the barrel confirmed the first-formed opinion that the gun had not been fired.

To return to the scene of the crime: The detective asked for any empty shells found nearby. The police had picked up a 25-caliber shell immediately behind the sedan but this did not completely satisfy the detective. He had been told by witnesses that four shots had been fired and since an automatic pistol ejects its shells immediately as each one is fired, there must be other shells in the vicinity. A careful search soon disclosed three more empty 25-caliber shells.

The next thing to attract the detective's attention was a back cushion, such as drivers frequently use, lying on the running board. Upon asking where it came from and where it was found he was informed that it was lying in the roadway under the running board immediately below the left front door. Apparently it had been dragged out by the victim when he opened the door to get out of the car. This served in great measure to refute the statement by certain witnesses that the driver of the sedan had left the car by means of the right-hand door. After asking a few more questions, the detective gave orders for measurements to be made of the exact position of the car relative to the curb and the nearby corner. A photographer was instructed to take pictures of the sedan from various positions, and also pictures of the entire block from the corner.

THE detective then went to work to examine the interior of the car for possible bullet holes, commenting upon the fact that, while no 32-caliber shells had been found, it was possible that a shot might have been fired by the driver of the coupé before the man in the sedan got out. His diligence was soon rewarded, for he found a small hole in the cloth lining on the inside of the left front door close to the handle. He carefully cut away the cloth and on tearing the lining he found a metal-patched 25-caliber bullet flattened against the door lock. It had distinct rifling marks and also appeared to have some blood on it when examined under the magnifying glass.

The detective now had in his possession the following knowledge: several conflicting stories told by witnesses; the fact that the back cushion had been found on the roadway under the left running board; the information that four 25-caliber shells had been found on the scene; and that a bullet had been lodged in the left front door of the car. His next procedure was to go to the hospital and examine the body of the driver of the sedan. It was found that a bullet had pierced the left wrist. This wound was accounted for by the bullet which had been found in the door of the car. There were three other wounds on the man's left side and when an autopsy was performed three 25-caliber bullets were removed from the body. Upon microscopic examination of these bullets it was found that each had six land and groove marks (see page 265 October 1930 issue of the SCIENTIFIC AMERICAN), the direction of which ran from left to right. Each bullet also had punched on it a small letter "w" indicating that it was made by the Winchester Repeating Arms Company. This small "w" linked the bullets with the shells which were all stamped with the mark of the same company.



Two views of the mushroomed 25-caliber bullet taken from the car

While all this work was going on and the police were busily engaged in building up a case, the driver of the coupé, fearing possible capture by the identification of the car which he drove, consulted with his attorney and decided to surrender himself. This he did, telling an apparently straightforward story of self defense. He claimed that the driver of the sedan had opened fire first, firing two shots at him. The driver of the coupé surrendered both his gun and his automobile. The car bore distinct scratches on the edge of the left-hand mudguard which coincided with scratches on the rear right-hand mudguard of the sedan. The pistol was a Spanish make 25-caliber automatic and was not loaded when surrendered but had powder smudges on the interior of the barrel. Furthermore a strong odor of powder indicated that the pistol had been discharged recently. The gun was turned over to the firearm expert and five test shots were fired into cotton waste. The bullets were recovered and an examination was made under a comparison microscope. It was determined beyond a doubt that the test shots, the three fatal bullets, and the bullet removed from the car door had all been fired from the same gun. (The methods used in reaching this conclusion were dealt with in detail in the October issue of the SCIENTIFIC AMERICAN.) It had already been determined, as described above, that the 32-caliber automatic had not been fired.

The evidence in this case was presented to the Grand Jury and its members were given all the facts determined by the scientific examination of the firearms. They failed to indict the defendant, on the ground that the driver of the sedan had evidently intended to shoot the driver of the coupé and that therefore the latter had acted in self defense. The members of the Grand Jury, however, expressed their interest in the preparation of the case and were deeply impressed by the scientific methods used by the Police Department in determining the facts.

IN order to complete the investigation and mark the case definitely "Closed" it was necessary to establish a motive. It developed that the driver of the coupé, several months prior to the commission of the crime, had delivered a large quantity of grapes to the other party, the value of which was 800 dollars. After repeated attempts to collect this debt, a summons to appear in court was served upon the purchaser of the grapes, who accepted the summons but gave a receipt, as it were, by striking his creditor in the face. The latter's dignity was severely hurt but he decided to use a more effective weapon than his fists. He therefore left as though he was completely defeated but planned a suitable revenge.

He drove directly to his office and took from his desk the 25-caliber automatic pistol. As he re-entered his car he noticed his debtor seated at the wheel of a sedan at a nearby corner. He realized then that he was in for trouble. Suddenly, so it appeared to the man in the coupé, the driver of the other car vanished. This apparent change in the situation reduced the vindictiveness of the driver of the coupé to fear, and he thought it a good opportunity to get away safely. He started away from the curb with a burst of speed and as he passed the sedan he saw his opponent straighten up from the seat where he had been hiding. The sedan too started off at great speed and the race ended as has been told. The customer paid the bill in full. It was he who staggered to the rear of the sedan with gun in hand and fell fatally wounded to the pavement.

The *Charles G. Black*, one of the largest tankers of the Standard Shipping Company's fleet. She has a tonnage of 20,500, and is 550 feet 3 inches long, 72 feet 2 inches beam

WHEN CRUDE OIL CROSSES THE SEAS

By HENRY W. HOUGH

MORE new merchant ships now are under construction throughout the world than at any time in recent years. The present total of 3,265,929 tons exceeds by more than 100,000 tons the level attained just prior to the World War. This notable peace-time revival in one of the world's greatest industries has been even more marked in the United States than in other maritime countries. The tonnage of new vessels under construction in American shipyards still is only about one eighth of that laid down in yards in Great Britain and Ireland, but during the last quarter, the United States advanced from fifth place to third, and now is hard on the heels of Germany, which holds second place in the tonnage of new ships being built.

Amid this quickening interest, particularly notable is the recent impetus in the construction of tank ships. The increase is attributed to the world-wide and ever-increasing demand for petroleum products and other bulk cargoes, such as creosote, molasses, coconut oil, turpentine, whale oil, and vegetable oils. By far the most important of these liquid cargoes is crude oil. Much gasoline, fuel oil, and other refined petroleum products also are transported in "tankers."

Of all the new tankers now under construction in America and abroad, perhaps the most interesting are the two new 18,000 ton ships being built at the Kearny, New Jersey, works of the Federal Shipbuilding and Dry Dock Company. These vessels are being constructed for the Standard Shipping Company, marine subsidiary of the Standard Oil Company of New Jersey, which owns and operates the world's largest tanker fleet. With the additional ships now being built, this great fleet will comprise 106 ships aggregating 1,105,528 tons, operating in all parts of the world but especially in American inter-coastal traffic.

The two new Standard tankers are said to represent the "last word" in design and equipment, and are expected to show a substantial saving in operating costs as well as in the initial investment. Their construction is being watched with interest by those interested in ships of this kind, because of a number of departures from standard design which are being incorporated.

THEY are 544 feet in length, 74 feet in width, and 40 feet in depth, with a draft, when loaded, of about 28 feet. They are single-screw ships, and will operate at an approximate speed of 11 knots per hour when loaded to capacity. Both are being powered with De Laval cross-compound steam turbines equipped with double-reduction gears of recently improved design, made by the same manufacturer.

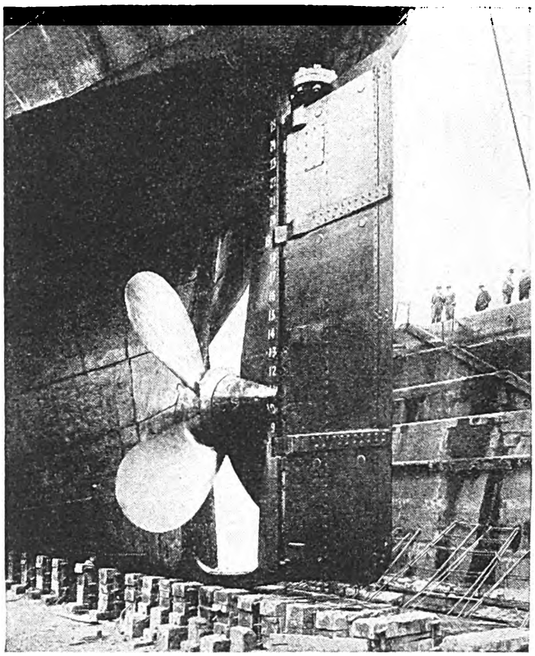
Oil-fired Babcock and Wilcox water-tube boilers will supply the turbines with superheated steam under 400 pounds pressure at 750 degrees, Fahrenheit, at the superheater outlet. All of the ship's auxiliary equipment will be operated electrically, including the cargo pumps and steering gear. Two 300-kilowatt turbo-generators will provide the electricity. These power plants follow the practice which has proved most satisfactory on land in central power station service, with turbines operated by steam at high pressures and high temperatures and the auxiliaries operated by electricity.

Perhaps the most interesting of the new features incorporated in these tankers is the revised arrangement of the boilers. Instead of placing the boilers in front of the turbines, as is the customary practice, they are located aft in the narrower part of the stern. The additional space made available by the new arrangement is of exceptional value in ships of this type, because of the tankers' characteristic location of the propulsive equipment in the stern, where the curving hull reduces the available space required for the various auxiliaries of the engine room.

In addition to increasing the space in the engine and boiler rooms, this arrangement permits the use of a flexible propeller shaft nearly three times the conventional length. A high degree of flexibility between the turbine and the propeller shaft is considered one of the paramount characteristics of an efficient marine power plant.

These new tankers are being equipped with the already famous "contra-rudder" and "contra-propeller." By using these stream-lined propeller hubs, stern-posts, and partially balanced rudders, an appreciable saving in fuel costs will be effected. At the former fuel consumption, the speed of ships is increased from 5 to 10 percent with this equipment. In addition, there is a reduction in torque on the rudder of from 30 to 40 percent, which reduces the strain on the steering gear and makes it possible to maneuver the ship more easily.

Tank ships are constructed with a number of compartments, formed by horizontal and longitudinal bulkheads.



Courtesy Th. Goldschmidt Corporation

Contra-rudder and contra-propeller, the stream-lined design of which saves much fuel

In the average tanker, the compartments are arranged as follows, working back from the bow: fore peak tank; fore hold for package freight and a tank for water ballast; cofferdam; cargo tanks; pump room; cargo tanks; cofferdam; bunker for fuel oil; space for boilers and machinery; and fresh water tanks. In addition to the deep cargo tanks, there are also "summer" tanks. These are long, shallow compartments situated above the deep tanks along the sides of the ship. They are used when carrying light cargo such as gasoline or naptha. Some tankers are built with two longitudinal bulkheads instead of one, forming a greater number of compartments of decreased width.

THE cargo pumps, usually located amidships, naturally vary in size and number according to the size of the ship. The output of each pump ranges from 150 to 400 tons per hour. The customary discharge pressure is between 50 and 100 pounds per square inch. In many installations, the ship's pumps are operated by steam, as are the winches, windlass, and other auxiliaries. In the new Federal-built tankers, all such equipment is electrically operated.

The pumps are used for unloading, "trimming," equalizing the cargo in the various tanks, and taking on and unloading water ballast when the ship is otherwise empty. When taking on a cargo, pumps on shore do the loading except in ports where gravity pressure can be used.

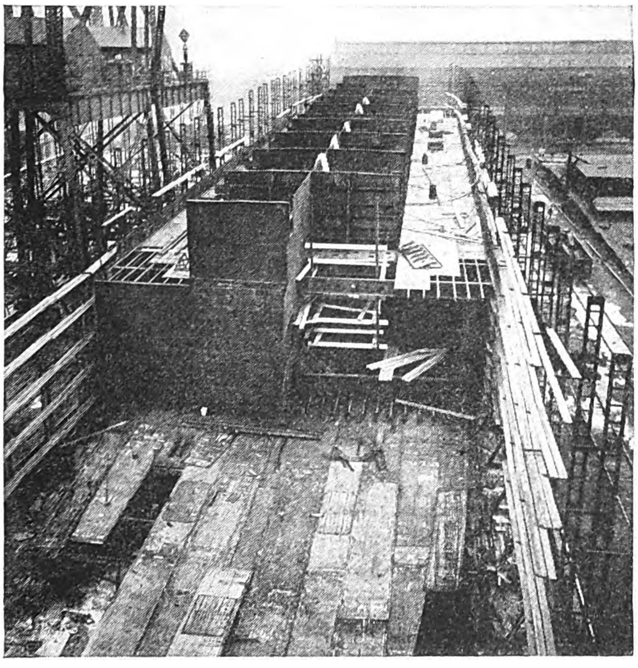
To load a ship properly with a liquid cargo is a task which requires real teamwork, good judgment, and long experience. Should the officer who is supervising the loading fail to give the shore pumpman the signal at just the right moment, the tanks may take on the appearance of miniature gushers. Cleaning the deck is not a pleasant task, after such an occurrence, and of course to lose oil is to lose money. More important, however, is the necessity of keeping the overflow from contaminating the water near the loading dock. To pour oil on the waters is an unpardonable offense in any port.

It requires only five or six hours to load or unload the largest of the oil tankers, some of which have a capacity up to 150,000 barrels. Consequently, ships of this type are able to spend practically all their time at sea, with waste time reduced to a minimum.

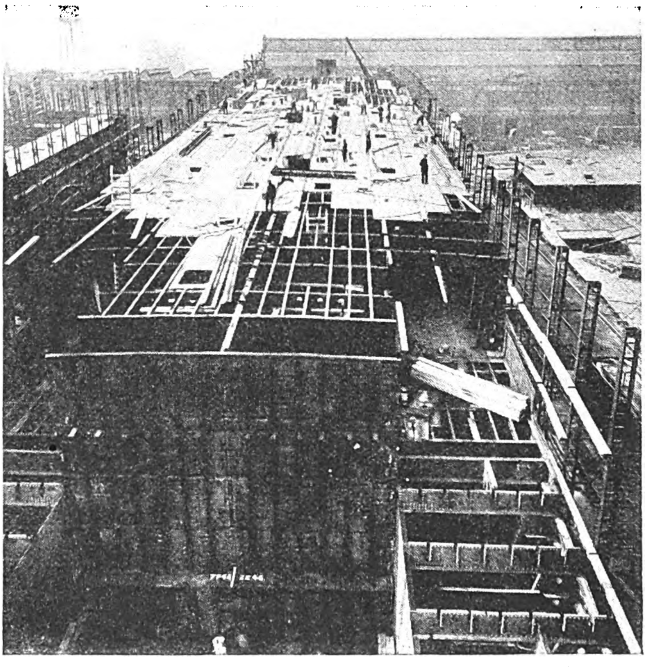
American oil was transported across the Atlantic ocean as long ago as 1861. Before the days of steamships, tankers were busily crossing the seven seas.

For a long time, domestic transportation of petroleum and its products was handled almost exclusively by river barges and railway tank cars. With the construction of extensive underground pipe-line systems, it seemed that oil could be transported almost any distance by that method. Economy, however, added another chapter to the story.

The longest of the oil pipe-lines was a 1700-mile trunk line extending from the mid-continent fields to Bayonne, New Jersey. Originally it was an oil line, transporting the raw material from the oil fields to refineries on the eastern seaboard. Now it transports gasoline—the finished product—from the eastern refineries to one of the most important consuming areas in the middle-west. Thus the order of supply is reversed, for the oil companies have found it more economical to supply their eastern refineries with crude oil brought by tanker from pipe-line terminals at ports in Texas, Louisiana, California, Mexico and elsewhere—a task for which these new tankers will soon be launched—and pipe the finished product into the interior. "The old order changeth, yielding place to the new."



Construction of cargo tanks of a new Standard tanker, with longitudinal and horizontal bulk-heads in place



Later view of construction of tanker with tanks partially covered with plates, and apertures for filling and emptying

TRAVELING HOME FOR 'PHONE LINEMEN

By C. W. GEIGER

No longer does the lineman whose duties take him to the wide open spaces and the sagebrush wastes of Nevada have to shiver through long nights in zero weather. No longer does the truck driver have to haul water 14 miles to camp. No longer—ah, well, the old-timer who did his hitch in '14 when they built the T-C lead shakes his head and mutters something about times not being what they used to be. He mutters something about the coming generation getting softer, or having it soft, or some such remark that betrays a bit of wistful reminiscence rather than envy.

These comfortable, clean berths are a vast improvement over the camp quarters formerly used

For today telephone men in the sagebrush country are residing in "private" cars. They are real, honest-to-goodness private cars. These cars were purchased by the Pacific Telephone and Telegraph Company from the Southern Pacific Railroad Company and remodeled under the supervision of the telephone company.

For many months construction crews from California have been "farmed out" on the desert. With the completion of each job, however, a new one was devised, for work in the Silver State is no longer a seasonal activity, and the growth of the telephone business has demanded all-year activities.

When it is 10 degrees below zero, Nevadans consider it a light frost, so with the ever-increasing demand for telephone circuits, some steps had to be taken to provide adequate living quarters for Californians engaged in desert work. When it was definitely decided what was required, the Supervisor of Supplies of the Pacific Telephone Company began negotiations with the Southern Pacific Railroad Company and, as a result, the linemen now have a complete "home sweet home" of seven cars, comprising material, water, commissary, kitchen and dining, recreation, sleeping, and foreman's cars. The whole unit will take care of 40 men.

The Threlkeld Commissary Company, which provides the meals, occupies one car, remodeled to provide a commissary and sleeping quarters for the Chinese cook and the waiter. From this car the kitchen help can walk into the dining car, which has been rebuilt to provide a kitchen the full width of the car with an adjacent horseshoe counter.

Following the dining car is the recreation or club car, which is equipped with a radio and tables for cards and reading. What was formerly the kitchen of this car, when it was in active service on the railroad, has been remodeled into a bathroom de luxe, featuring heating arrangements better than some bachelors have at home. Forty minutes before the "gang" gets in the car to "ablute," the "Chief Steward" starts the works and then—hot water for everyone. For the more fastidious, there are tub and shower baths.

After the recreation car comes one of the sleeping cars, which is provided with double deck berths the full length of the car. The next car is the foreman's car, equipped with single berth cots, and, located at one end, the foreman and clerk's sleeping and office quarters.

A two-kilowatt automatic lighting unit furnishes the electricity for lighting. When any light is turned on, it automatically starts the motor and instantaneous lighting is then furnished throughout the cars as required. Turning off the last light stops the motor. To provide water throughout the train, a pressure pump has been installed, hooked up with the lighting unit. This scheme gives water pressure equal to the usual city pressure.

The railroad car home is indeed a tribute to the efforts of the management of the telephone company to provide adequate protection and accommodations for those whose duty takes them to the barren wastes.

Another and similarly equipped special train with 80 men on board is being used in building a long-distance telephone line across the sands from Barstow to Las Vegas. The project, involving 826,000 dollars, will provide 85 simultaneous talking circuits between southern California, the Hoover Dam territory, and certain desert towns that have never yet had telephone service. The circuits will be extended later to Salt Lake City. Pressing telephone requirements have developed in this section of the west, and the specially equipped construction train departed as the best answer for the situation.

Included in the train are three sleeping cars, a dining car, a commissary car, a bath car, a supply car, and a water car. Although the men will be in the warm environs of the desert for several months, each day's toil will be forgotten in the 12 shower baths in the bath car.

The men have their own lighting system aboard, together with electric refrigeration. Ice cream sundaes on the fringes of Death Valley loom as possibilities, according to the head of the commissary department, who has planned to deliver approximately 20,500 meals to the hungry workers while en route.

Electric fans are also installed in each of the coaches. The dining car contains a table more than 60 feet long, capable of seating the entire personnel. The club car contains regular day-coach chairs, card tables, a phonograph, and other equipment to make the desert headquarters home-like. The train was purchased by the telephone company and the interiors of the coaches were refitted to suit the needs of the expedition.

These modern telephone pioneers began their activities just east of Barstow. Augmenting the telephone train are 10

AVIATION IN 1930

By PROF. ALEXANDER KLEMIN

In charge, Daniel Guggenheim School of Aeronautics, New York University
Associate Editor, *Scientific American*

AIRSHIP enthusiasts have been greatly encouraged by the year's developments. In Akron, under the auspices of the Goodyear-Zeppelin Corporation, the 6,500,000 cubic-foot airship *Akron* is advancing rapidly. Seven main frames, and 18 intermediate frames are in position, representing 525 feet of the ship's total length of 785 feet. This dirigible has been called the "airship of 6,500,000 rivets"; stood on end it would be equivalent in height to a skyscraper of 80 stories.

Driving rivets in the airship is not the noisy process we associate with the construction of a skyscraper. The dural rivets, heat-treated in an electric furnace, are taken from the furnace, immediately quenched, and then simply squeezed into position by a manually operated tool.

The airship is to be delivered to the Navy Department in the spring of 1931. With its swiveling propellers, speed of 80 miles per hour, and unequalled dimensions, the *Akron* will mark a distinct epoch in airship development.

THERE are at present only two airship building corporations of importance in the United States. One of these, the Aircraft Development Corporation of Detroit, is actively pursuing its experiments with the metal-clad type of airship in which a thin metal covering, about eight thousandths of an inch in thickness, replaces the conventional rubberized fabric covering of today. The metal-clad airship built by this company and delivered to the Navy's Airship station at Lakehurst, has shown up excellently in service and has successfully demonstrated that the difficulties expected from the very thin metal covering are really non-existent.

It is understood that the duPonts, in conjunction with yet another lighter-than-air company, are producing a synthetic material which will replace the expensive goldbeaters' skin (made of animal entrails) and will reduce the permeability of the gas bags to helium to an almost negligible quantity.

Small airships for private or commercial use have been few in number to date. They have possibilities, however, and it is intriguing to learn that Captain Anton Heinen, the airship pilot employed by the Navy Department in the construction and operation of the *Shenandoah*, is planning to build a number of small airship yachts. These little airships are to be only 104 feet in length with a gas capacity of 39,600 cubic feet. They are designed to have a top speed of 65 miles per hour and are to cost less to operate than an automobile! The plans also call for the use of a detachable passenger car which can operate under its own power as an automobile. This of course would meet the great difficulty of transportation to the airport. It remains to be seen whether the technical difficulties involved in such independent operation can be overcome.

ALTHOUGH the general business depression during the past year has affected aviation adversely, the developments within the industry give promise of a bright future. On these pages Professor Klemin presents a brief yet thorough survey of the situation.—*The Editor.*

Still another encouraging feature of the airship situation is the fact that the proposed airship line between Spain and South America, under combined German, Spanish, and South American auspices, is apparently coming to a head. At any rate Captain Eckener, full of energy and enthusiasm after his successful voyage 'round the world, has definitely begun the construction of an airship for this service. The new airship, the *LZ-128*, is to be finished by the end of next summer. She is scheduled to be 815 feet in length, with a maximum diameter of 130 feet, and a displacement of 5,250,000 cubic feet. Four power gondolas are to be placed on each side of the airship, each equipped with two Maybach motors of 500 horsepower. The airship is planned to be used mainly for mail purposes and is not to be equipped with any degree of luxuriousness. The Spain-South America line is regarded as an even more promising field for the airship than the Germany-Lakehurst route, because the saving of time over the 17-day steamer service is likely to be overwhelming.

The British, on the other hand, are more than satisfied with the flight of the *R-100* from Cardington to Montreal and back. The voyage from east to west, beginning on July 29th, took 79 hours of flight, with eight hours delay due to repairs in flight. The return trip of 57 hours 5 minutes was very close to the record time of the *Graf Zeppelin*. The *R-100* navigated successfully through fog, and when it was encountered on the voyage also demonstrated the success of a very useful new device whereby water deposited on the cover was collected by a series of special drains leading to a cistern. More than two tons of water were collected in this manner in the course of one morning. This ship was constructed by the Airship Guarantee Company of which Commander Sir C. Dennis Burney is the guiding spirit. As the result of close analysis and of the experience achieved in this successful voyage, Commander Burney predicts large profits on the investment in a regular line.

THE trip of the *R-100* constitutes the eleventh crossing of the North Atlantic by airship, with some minor mishaps it is true, but with not a single fatality on any of the crossings. There would appear to be a good deal in favor of the opinion that the airship is a suitable medium for trans-oceanic travel.

The year has been marked by comparatively little news of helicopter development—with one outstanding exception, the announcement of completion of the Curtiss-Bleecker Helicopter.* The possibilities of the helicopter or direct lift type of aircraft are very great. It is obvious that the ability to rise vertically from a small plot of ground and to land at will in equally restricted territory is very valuable. While it is inconceivable that the helicopter should compete with the airplane for load carrying at high speed, it would be a very valuable auxiliary in air transport work. For military or naval air forces the helicopter's ability to hover over one spot would ensure accurate and deadly bombing. With these possibilities in mind much money and effort and ingenuity have been spent in all civilized countries on the production of a helicopter. Nowhere have really conclusive results been yet reached.

---

*For a description of this helicopter see *Scientific American* September, 1930, page 214.

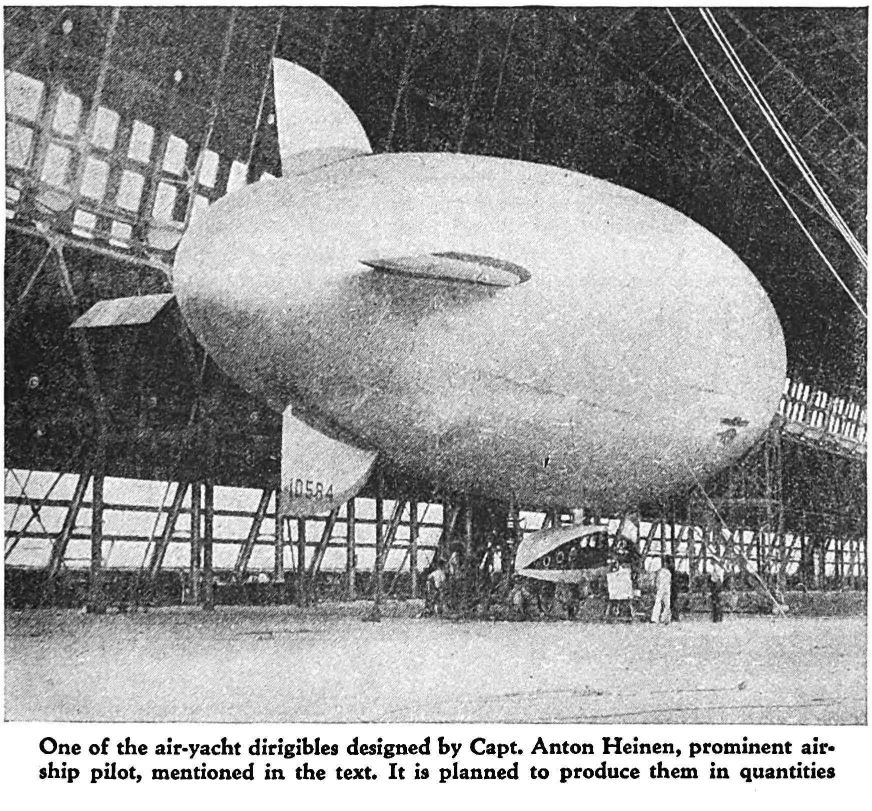
As aeronautics progresses more and more, it cannot be expected to provide us with so many thrilling novelties as in the past. Still there have been a good many novel developments even in this year of general aeronautical depression. One of the most striking is the provision of a parachute for the support of the entire plane, developed by the Russell Parachute Company and successfully tested on a Parks biplane of the Detroit Aircraft Corporation.†

On the first test, the ship landed in a tree, yet the only damage sustained was that of a broken propeller and a bent landing gear axle. There is no doubt that if the plane 'chute proves entirely practicable it will add greatly to the confidence of the traveling public.

At the same time manufacturers are not neglecting other ways of providing parachute facilities for the traveling public. For example quick-release parachutes have been successfully tried out in recent months. (See page 392, November, 1930, Scientific American.) The traveler is provided with a comfortable though sturdy jacket at the front of which there is a ring. The parachute is placed conveniently at hand in the cabin; a hook on the parachute can be attached to the ring in an instant. It is true that only a short time ago a girl of 16 jumping from a cabin plane forgot to pull the rip cord and was killed, and it is true that passengers as a group will not take readily to the parachute. Still its possibilities in emergencies are well worth experimenting with.

The only type of aircraft we can recall which may be classed as completely a novelty is the rotor seaplane recently built at Mamaroneck, New York. Considerable mystery attaches to the construction of this seaplane. Instead of the ordinary wings, two cylinders or rotors are placed above and on either side of the fuselage, and are turned by suitable gearing from an engine placed in the fuselage; a second engine drives a conventional propulsive propeller. When the rotors are turning and the seaplane as a whole is in forward motion the rotors give a powerful upward or lifting force. Their action is similar to that of the Flettner rotors used in the Flettner rotorship, *Buckau*. While the daily press grew quite excited about the possibilities of the rotor airplane, it must be remembered that while rotors are very powerful in lift, far more powerful than ordinary wings of the same area, they are also far less efficient. That a rotor airplane can be made to fly is quite likely. That a rotor airplane can be made reasonably efficient is very doubtful. (For a fuller description, see page 392, November, 1930, Scientific American.)

The year's activity in design, although somewhat curtailed by the general slump in aviation, has brought out several new types of planes. The Daniel Guggenheim Safe Aircraft Competition was instrumental in bringing out the Curtiss *Tanager*, the prize winning plane of the competition. This plane has brought several fine developments to the eyes of the designer, notably the slots, flaps, and floating aileron. The added lift and speed range due to the slot and flap combination has proved very encouraging. (For details of the *Tanager*, see page 232, March, 1930, Scientific American.)



One of the air-yacht dirigibles designed by Capt. Anton Heinen, prominent airship pilot, mentioned in the text. It is planned to produce them in quantities

In the light racing and sport plane field, the *Mystery S*, a low wing monoplane designed by the Travel Air Company, has created quite a stir. The *Mystery S* is a typical low wing monoplane streamlined to the highest possible degree. It has incorporated every known device for the reduction of drag such as tapered wings, wheel fairings, elliptical fuselage section, and filleting of all sharp corners. The streamlining of the fuselage is carried through to the rudder, the bottom of which conforms with the shape of the fuselage. The amount of external bracing has been cut to a minimum and where necessary it has been done through use of streamline wire. The landing gear of the *Mystery S* is of unique design.

The shock-absorber strut is a combination oil and spring type held in a vertical N Strut which is attached to a wing stub. Each unit of the landing gear is fastened to its own wing and the wing stub of the opposite side. Most of the wheel and mechanism are enclosed in a neat fairing. The plane attains speeds in excess of 200 miles per hour equipped with a special 400 horsepower Wright Whirlwind. Many of the small ship manufacturers have followed in the steps of the Travel Air Company and are developing small fast planes but this ship still remains as one of the swiftest and neatest of designs.

A DECIDED trend toward increasing the payload with increase in size of the ship has been confirmed by the construction of several large ships. There is the Junkers *G-38* which has undergone several successful flights at Dessau, Germany. Although the construction of the *G-38* is of usual Junkers metal type, the depth of wing is such that the power plants and cabin passenger accommodations are wholly contained within it. Propellers are mounted out in front of the wing on streamlined bosses and driven by extended shafts from the motors. The plane will carry 32 passengers together with a cargo of freight and mail. Passenger cabins in the wings are available.

In America, the Fokker Company has developed the *F-32*, a large monoplane of usual Fokker construction carrying 32 passengers and having a payload of 8700 pounds. The plane is driven by four motors in two tandem pairs mounted out under the wings. Passenger accommodations are very luxurious and are capable of being made up as a Pullman for night service.

The Commodore flying boats which have been constructed by the Consolidated Aircraft Company and put into service on southern routes of the N.Y.

---

†For full description see *Scientific American Digest*, this issue.

R.B.A. Lines are also additions to the large plane class. These planes are luxuriously equipped for 20 passengers and can be made up for night service.

In the aerodynamics of the airplane there have been no revolutionary changes, but steady refinement and improvement. The ideal of the airplane designer is a flying wing, with everything enclosed as far as possible in the wing itself. The Northrup Company, of California, has carried us a step nearer this ideal. Northrup has designed a pusher airplane, very heavily tapered from root to tip, so that the root of the wing is quite thick, so thick in fact that the small nacelle in which crew and engine are placed is practically hidden in the wing. The Northrup *Flying Wing* is a pusher, with the propeller mounted behind the wing, and the tail surfaces carried on outriggers running from the wing. This is a decided step forward. (See page 389, May, 1930, SCIENTIFIC AMERICAN.)

Vincent J. Burnelli has continued his experimental work with a transport plane in which exceptional cabin space is provided. The Burnelli fuselage is twice as broad as the conventional fuselage, but it is given an airfoil form and thereby contributes to the lift. At the same time the two engines are mounted inside the fuselage, at its leading edge. It is claimed for the Burnelli principle that the relatively enormous passenger space is obtained without any sacrifice of aerodynamic efficiency.

THE Fokker Aircraft Corporation has also been working in the direction of the flying wing. A bomber recently tested has its cantilever wings of such thickness that the fuselage fairs completely into the wing at the root. At the same time the two Curtiss Conqueror engines also merge completely into the thick wing.

In the Boeing mail plane, the *Monomail*, a retractable chassis is another method of reducing resistance.

In discussing thick tapered wings, which provide such excellent spar depth to resist bending moments, it is often said that the drag of the thick wing must be greater than that of a thin wing with external bracing. We have the authority of R. J. Minshall of the Boeing Company for the statement that tapered wings are now available which have an intrinsic profile drag no greater than that of the thin wing of the past.

Another aerodynamic development which is meeting with increasing favor is the Townend ring. This is a simple ring a few inches in width, and of slight curvature along its width, which is made to surround the radial air-cooled engine. The Townend ring smoothes out the flow when broken up by the projecting engine cylinders and enables the air to keep streamline contact with the fuselage. The Townend ring achieves the same purpose as the somewhat more complicated Venturi cowling, and is much simpler to build.

In those landing gears which are not retractable, designers are making efforts to reduce resistance by putting "pants" or "spats" over the wheels or by using cantilever struts, just one strut to a wheel instead of the two or three struts previously employed. Some designers have tried fairings which enclose both struts and wheels. Another aerodynamic improvement consists in the use of fillets between wing and fuselage. Experiments at New York University have given an exact rule for the design of such fillets or fairings.

In general the airplane is rapidly approaching its ideal streamline form.

ONE of the most important problems engaging the attention of airplane designers to-day is that of metal covering instead of fabric covering for both the wings and fuselage of an airplane. Fabric covering has the disadvantage of poor maintenance and durability. Metal covering is unfortunately very heavy, even if the thinnest sheet is employed. Since the airplane is under very strict weight limitations, it is only desirable to use metal covering provided the covering itself contributes to the strength. Unfortunately thin metal sheet will not develop anything like its theoretical strength because of local failure termed "crinkling" when the sheet is in compression. The Navy Department and the Army Air Corps are both giving much attention to the problem of the metal-covered fuselage, and in time disconnected efforts of various designers should lead to more accurate knowledge.

The large airplane of the future should have a structure similar in some respects to the structure of the ocean liner, in which the metal plating is already so thick that it can be confidently taken into account in the calculations of strength.

One of the most marked tendencies in the aircraft engine development for the year was the increasing number of inverted, in-line, air-cooled engines of the lower horsepower range which appeared. At both the St. Louis and the Detroit aircraft shows this type of engine was well represented.

Among the newer ones of this type we have the Chevrolair D-6, a six in-line, manufactured by the Chevrolair Motors, Inc. The engine is rated at 170 horsepower at 2000 revolutions per minute. Another of the interesting engines of the inverted type is the Hi-Drive Ensign engine manufactured by the American Cirrus Company. This is equipped with a DePalma super-charger and is rated at 110 horsepower at 2100 revolutions per minute.

THE Fairchild Aviation Corporation have also introduced an inverted six in-line of 110 horsepower.

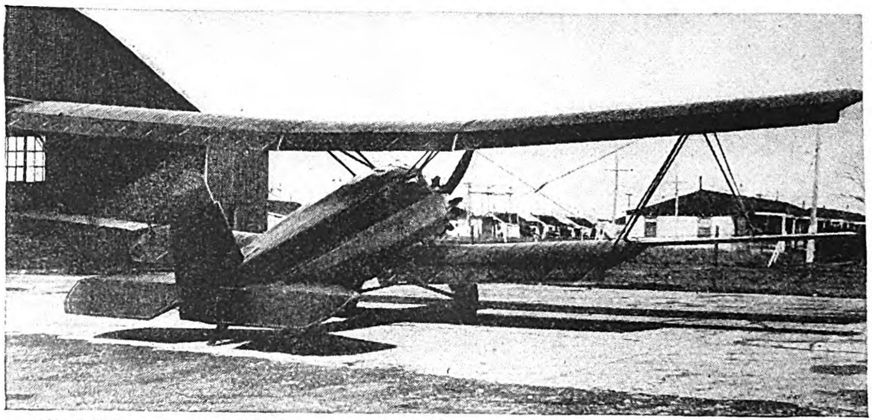
Engines of this type (inverted in-line) are somewhat heavier than radials of the same horsepower, but their greater simplicity, easier accessibility, better stream-lining and vision qualities are making them more and more popular.

The Packard Diesel, over its first trial stages, is apparently finding acceptance among the aircraft designers and builders. Several transports, including Ford tri-motor and others, have offered planes using this engine.

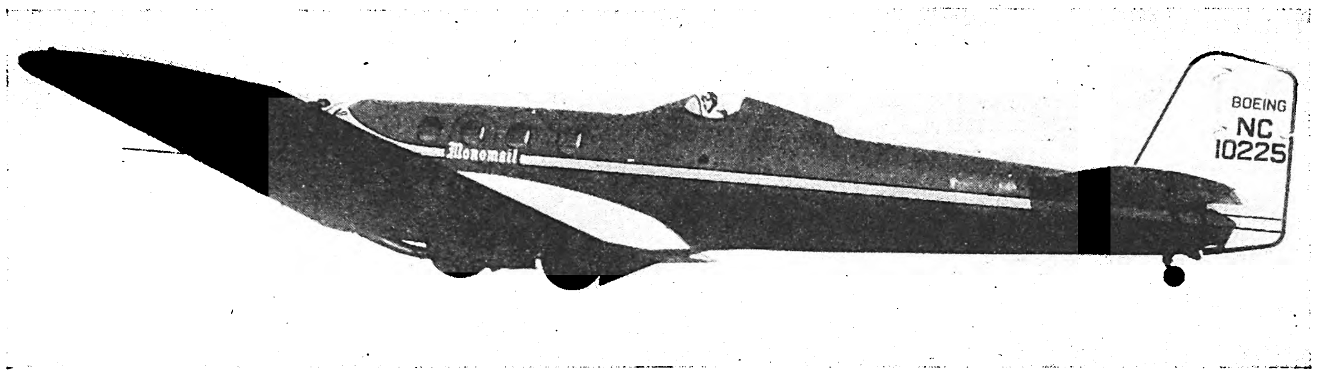
The L-head engine so popular in the automotive field, has lately entered aviation. The MacClatchie Manufacturing Company has placed a seven cylinder, radial, L-head engine on the market. The difficulty of cooling these L-head air-cooled engines has apparently been overcome in this engine. It develops 150 horsepower at 1900 revolutions per minute and weighs 400 pounds.

Another interesting development among the aviation engines is the increasing number of two-cycle engines that are making their appearance. Several small motors on this principle, of about 30 horsepower, designed for the light plane, have been developed.

The two-cycle engine undoubtedly has great possibilities in the air-



A striking view of the *Tanager*. The floating ailerons and the wing flaps are plainly visible. This particular plane was destroyed by fire while on the ground



The retractable landing gear on the *Monomail* is said to add 25 miles per hour to the plane's speed

craft field. This is especially true in regard to Diesels. The two-cycle Diesel offers many advantages over the four-cycle gas or oil engine or the present two-cycle gasoline engine. The present two-cycle design has four disadvantages: poor scavenging, delicate mixture control, low volumetric efficiency, poor fuel economy. The so-called "solid injection" of fuel would probably remedy this. The four-cycle Diesel has the disadvantages of weight, high consumption of lubricating oil, and mechanical complications.

THE year has witnessed remarkable record-breaking performances. The re-fueling flight of the Army plane *Question Mark* ushered in a contest to see which plane could stay aloft the longest. Notable among the many flights was that of the Hunter Brothers at Chicago who stayed up for 553 hours in a Stinson *Detroiter.*

Their record was broken by the former record holding team of O'Brien and Jackson who regained their title by staying in the air some 743 hours in a Curtiss *Robin* plane. These flights proved beyond all doubt the feasibility of long, refueling flights.

Two other record breaking flights were made during the year. The first of these was that of Lieut. Apollo Soucek of the United States Navy who reached an altitude of 43,166 feet in a Wright *Apache* plane. The Navy personnel had been experimenting for more than a year on improving the performance of the plane and no factor was overlooked which might raise the ceiling of the plane. When a study of the research data is complete the flight will assume a greater meaning to aviation.

The second flight was that of Capt. Hawks who put up a new trans-continental record in his 12¼ hour coast-to-coast flight. The flight was made in a Travel Air *Mystery S*, the actual air time being 11½ hours, three quarters of an hour being consumed in three refueling stops.

One of the reasons for the disappointing showing of the aviation industry this year is the slow growth of private flying. The reasons are easy to find. In spite of the results of the Guggenheim Safe Aircraft Competition, few manufacturers have sought to embody in their airplane designs the latest aerodynamic safety devices. Well-informed opinion is that while planes are much safer than they used to be, they are still far from the ideal.

Airports and fields are much more numerous than they used to be, but still far from being immediately accessible. A plane is expensive to purchase and expensive to maintain. All these obstacles will disappear, but they have not disappeared as yet. The position of the private plane owner is not at all that of the automobile owner but rather that of the motor-boat owner a few years ago, who had to exercise skill, knowledge, and determination to derive pleasure from his craft.

A RECENT survey of the situation by *Aviation* gives a very fair picture of existing conditions. The typical private plane owner of to-day is a man in his early thirties, with an average income of about 8000 dollars a year. There is no typical occupation for the plane owner. He may be an advertising man, a junior executive, a broker, publisher, or salesman. He flies because he likes it.

Those men who purchase airplanes from a business point of view seem to find their investment a disappointing one. The average monthly flying time is only 13 hours and 24 minutes or about 160 hours a year. Flying is generally a matter of Saturday afternoons and Sundays. Some owners turn their craft over to professional pilots for passenger-carrying work during the week in order to defray expenses. Crack-ups are fortunately few. The enthusiasts who fly for pleasure know their business as a rule and they are not under compulsion to fly in all weathers as are air-mail pilots, for example. With this short flying time per year, and the rapid obsolescence of the modern plane, the question of "trade-ins" will certainly bother the trade in the very near future.

Owners find the maintenance of their craft quite onerous; as it is always necessary to inspect control wires, gas lines, landing gear, and so on, some 28.6 percent of the owners employ professional help.

The most popular type of privately owned plane is the three-seater open cockpit machine, with an air-cooled engine of between 150 and 225 horsepower. It is expected that the cabin plane will take the place of a good many of the open cockpit machines, and manufacturers are anticipating this change in demand. In spite of the fascination of the flying boat and amphibion, few private owners purchase such craft. The drawback is in expense. It is gratifying to see that a few manufacturers are turning their attention to inexpensive amphibions.

Aviation country clubs are a splendid social outlet, but the expenses of membership added to the flying expenses have checked the growth of this type of organization. The most promising line of attack would be the formation of flying clubs on the English model clubs where inexpensive, low-powered machines are employed, general expenses are restricted to essentials, and no attempt is made to provide a luxurious social atmosphere. The many English flying clubs have of course been fostered by direct government subsidy.

THE present status of aviation safety is naturally a matter of considerable public interest. Perhaps the most authoritative statement on the subject yet issued is the Report of Committee on Aviation Statistics of the Actuarial Society of America, which was compiled with the co-operation of many governmental and private agencies. It is impossible to present even in summary the findings of this report, which deals with every aspect of the subject, but the comparison with railroads will give a graphic view of the situation.

The Accident Bulletin of the Interstate Commerce Commission for the year 1928 shows a rate of .003 passengers killed per million railroad passenger miles. Only about one fifth of these

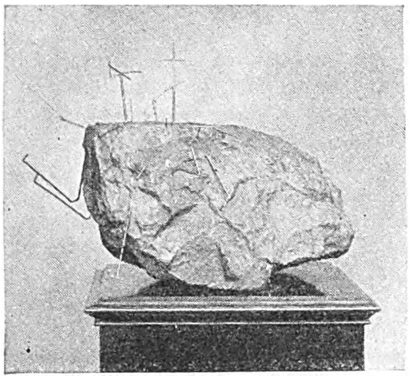
HUGE LODESTONE SPECIMEN

An extraordinary specimen of lodestone, weighing more than 400 pounds, and possessing unusually powerful magnetic strength, has been placed on exhibition in the department of geology at Field Museum of Natural History. The huge natural magnet comes from the Wasatch Mountains in Utah.



The average boy who likes to mystify his friends would give his last cent for a small piece of this 400-pound natural magnet from Utah

Lodestone led to the invention of the magnetic compass by the Chinese in the 12th Century. It is one variety of the mineral magnetite which has the property of attracting iron and other metals. A steel needle placed in contact with a lodestone will in a short while become so magnetized that, if free to move, it will point toward the north pole. It was observance of this fact that suggested the compass.

The attraction of the lodestone for iron was known hundreds of years before the polarity of the mineral was discovered, according to Dr. Oliver C. Farrington, curator of geology at the museum.

"Thales of Miletus (630-550 B.C.) mentions this power of lodestone as do a number of the later Grecian sages," states Dr. Farrington. "There is a fable that the discovery of the lodestone was made by a Cretan shepherd who noticed that his iron-pegged sandals and iron-shod crook clung to the earth. Digging into the ground he found lodestone.

"In classical times and during the middle ages, extravagant tales based upon a misconception of the power of lodestone were current. There were stories of magnetic domes which held statues of iron and even of brass suspended in the air, and there were accounts of mountains of lodestones which drew all the iron nails from ships which ventured near them, so that vessels sailing those seas were obliged to use wooden pegs for nails.

"Discovery of the compass has been attributed to many peoples of Europe and Asia. Many accounts of the early use of the compass are now believed to be mythical. One of these credits the Chinese emperor Hoan-ti with constructing in the year 2637 B.C. a chariot on which was a female figure which always pointed south, and there are other Chinese accounts of the use of these 'chariots of the south' at various times antedating the Christian era. Some European authors seem to indicate an occasional use of the compass as early as the 3rd Century but the first authentic records of its use do not antedate the 12th Century. Shortly after this time the compass came into general use by mariners. The first compasses were magnetized steel needles which were fastened to chips and reeds and floated on water."

◆

THE CHEMISTRY OF RIPE OLIVES

We have often heard that one has to cultivate a taste for olives, but while we readily confess to a weakness for the more common green olive, we have never been able to get up much enthusiasm for the ripe, or purple, variety. A possible explanation for this prejudice came to our attention recently in reading an article in *Industrial and Engineering Chemistry* by James G. Vail, vice-president of the Philadelphia Quartz Company. Mr. Vail informs us that ripe olives are treated in a solution of caustic soda before they are considered fit to eat. Now, any chemist can tell you that when you treat olive oil with caustic soda you get castile soap. With that fact in mind, it suddenly dawned on us why we never cared for ripe olives.

Actually, of course, if any soap is produced by this caustic treatment it is only in infinitesimal amounts. The subject is of interest, however, because Mr. Vail has discovered that a sodium silicate solution, which will not saponify the oil of the olives, seems to serve just as well as the customary caustic soda. Indeed, by using silicate solution, the olives may be allowed to ripen further on the tree and still yield a firm texture. The flavor of the fruit treated by the new process is said to be better. —*A. E. B.*

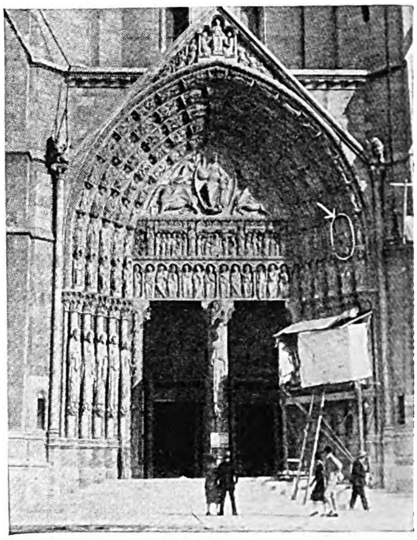
EINSTEIN, LIVING IMMORTAL

Not that Einstein "needs the publicity"; or that the fact that most men of science regard him as the greatest scientist, fit to rank with Newton, really requires constant reiteration; but because the editors from time to time receive communications from persons who either request confirmation of his high standing in science or, as sometimes occurs, wish to have their private opinion confirmed that he is a "faker" (as one rather excitable anti-Einsteinian repeatedly put it), attention is called to the recent tribute of the Riverside Church in New York which has chosen to include a carved figure of Einstein with those of the world's very greatest on the tympanum of the doorway of its new edifice.



A white oval has been marked on this illustration to show the location of the carved statue of Dr. Einstein over the main portal of the Riverside Church, New York City

Einstein is the only living person thus to be honored. The action of this church brackets his name with those of Socrates, Plato, Aristotle, Descartes, Spinoza, and Kant, the philosophers; Moses, Buddha, Saint Francis of Assisi, Luther, and Calvin, the religious leaders; and Galileo, Kepler, Newton, Faraday, Darwin, and Pasteur, the greatest scientists of all time.

The vast majority of men of science will concur in this selection. We believe that the statement of the physicist Heyl, that the majority of men of science qualified to judge—the physicists and astrophysicists—tentatively accept the Einstein Theory, will bear up under unbiased investigation.

Perhaps the fact that the newspapers have "made so much of" Einstein has tended to confuse some of the people. Certainly, at any rate, there is enough precedent—newspapers taking charlatans seriously—to make this kind of judgment seem plausible. But in this case the newspapers are right. Whoever permits himself to believe that Einstein is not looked up to by men of science should stop taking seriously the vitriolic phrases of a few superheated anti-Einstein cranks and should go among men of science where they are likely to obtain a new orientation.

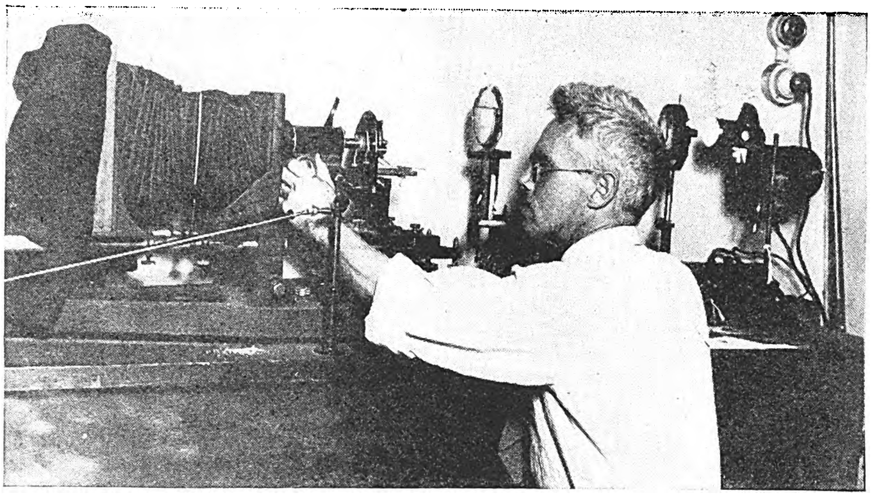
Another naïve question sometimes is asked: "Is Einstein really Jewish?" Einstein is a Jew.

EXPERT FINDS WAY TO PHOTOGRAPH SMALLEST LIFE

THE tedious work on the part of artists in illustrating minute forms of animal and plant life which can only be seen through a microscope, has finally been overcome by J. G. Pratt, scientific photographer for the United States Department of Agriculture.

Heretofore biological subjects could only be photographed satisfactorily from 10 to 15 times their natural size, which was not sufficient, and such subjects have always been drawn by artists, requiring hours of labor looking through a microscope, with little assurance that the resulting illustration was true to nature.

The difficulties encountered in photography at high magnification have been the flatness of field and the lack of proper illumination. Above 10 or 15 diameters the exposures are so long as to be impractical, and the short focus lenses required do not give sufficient depth of focus. That is, if a tiny insect were magnified sufficiently to see what it looks like, only a portion of its back would be sharply defined, the rest being hazy and distorted.



Mr. Pratt at work on his new equipment for photographing small life

After years of research Mr. Pratt has just developed a lighting device which is many hundreds of times stronger than sunlight, and also lenses which give great depth of focus, making possible the photography of animal and plant subjects up to as high as 300 diameters.

Mr. Pratt states that photo-micrography at such extreme magnification has heretofore been confined to metallurgy, on subjects which are flat and reflect a great amount of light; and that the new development should revolutionize the illustrating of biological subjects, which have considerable depth and reflect little or no light. He says that where previously the exposures for a magnification of 10 diameters took several minutes, only a few seconds are required for as much as 200 diameters with the present lighting device.

ULTRA-VIOLET TRANSMITTING GLASSES

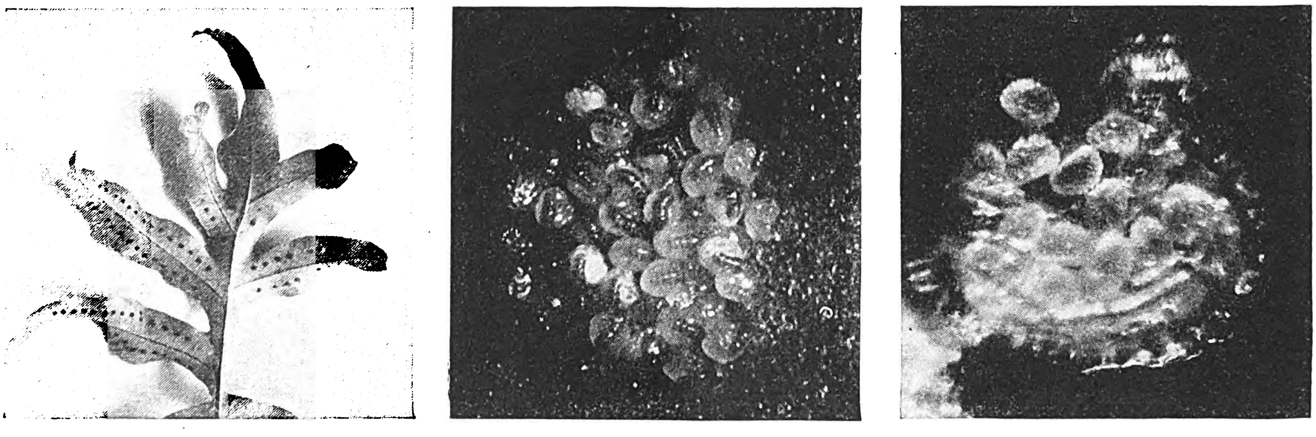
THE Council on Physical Therapy of the American Medical Association has made available a study of the value of glass of various types for transmitting ultra-violet rays. Dr. W. W. Coblenz of the Bureau of Standards in Washington, who is a member of the Council, points out again that ordinary window glass cuts off the ultra-violet rays, transmitting only 1 to 2 percent and being completely opaque to radiation of the shorter wavelengths. The maximum value of ultra-violet rays appears to be in the wavelengths from 297 to 302 millimicrons. Only a weak effect, if any, is obtained with longer wavelengths.

So far as the prevention of rickets is concerned, only window glass which has a transmission of 30 percent or higher of wavelengths of 302 millimicrons will give protection. It is understood also that the amount of ultra-violet received from ordinary sunlight is modified by altitude, latitude, time of day, the season of the year, and the amount of smoke. Obviously therefore only glass that will transmit ultra-violet freely is of any use. In the ordinary home it is perhaps better to do without window glass altogether for the room in which the child is to be sunned, and to use instead some sort of substitute.

The various devices for producing ultra-violet rays have been standardized by the Council on Physical Therapy of the American Medical Association, and inquiries concerning any special variety of lamp are answered with statements as to actual virtues in providing ultra-violet.—*M. F.*

CHILDISH DRAWINGS ON WALL OF ROMAN HOUSE

ONE family of ancient Rome would no doubt be greatly entertained if it could see archeologists of 1930 poring over the scrawled drawings made on the walls of their house. The drawings, recently discovered, are such as children of ancient

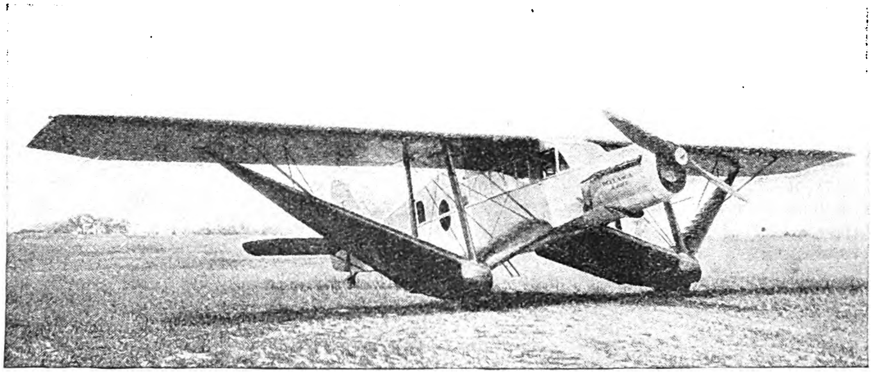


At the left is shown the frond of a fern with its fruit dots or spore clusters. In the center is a single fruit dot magnified 30 times. The small band resembling a worm on each spore case is known as the annulus. At the right: single spore case magnified 200 times, as the annulus is contracting and scattering the spores. All were photographed by Mr. Pratt

Rome, or any other time and place, enjoy scribbling on a handy piece of clean wall space.

The house of these wall decorations stood in the famous Appian Way about the time the Roman Republic became the Empire of Rome. Its ruins have lain buried beneath almost 40 feet of earth, and a Church of San Sebastian stands over the site.

Prof. Francesco Fornari, Roman archeologist who has been studying the mural sketches, sees in some of them pictures of fighting gladiators armed with shields, spears, and swords. Another sketch is believed to show an individual being burned. Rows of long and short lines, rising before this person, indicate flames, and there are soldier-like figures on each side who appear to be stirring up the flames with their spears. It is considered likely that the drawings were made by the children of some Roman fighter's household.



The Bellanca *Airbus* has a novel system of wing trussing

Other parts of the walls are adorned with frescoes done by more professional hands. —*Science Service.*

THE BELLANCA "AIRBUS"

G. BELLANCA of the Bellanca Aircraft Corporation is a designer who can be relied upon to produce original and worth-while modifications from standard practice.

For the designer of transport airplanes, there are two outstanding problems at the moment. One is to give the operator a greater payload for a given horsepower, thus making operations more economical—but without reducing speeds. The other is to provide him with a craft which will enable him to take full advantage of the Watres Bill, under which the Postmaster General can hire space in passenger-carrying planes, and which, therefore, necessitates the construction of planes to carry both mail and passengers.

The Bellanca *Airbus* certainly appears to meet these requirements by excellency and originality of design.

The main wing, mounted on top of the cabin, is similar to that of a conventional braced-wing monoplane with the exception that each wing is divided into two panels. The inner or center section panels of the upper wing, in conjunction with the lower stub wings, form the inner bay and are joined together by struts of round, chrome-molybdenum steel tubing, faired with balsa wood. From the outer end of each stub wing another lifting surface called the auxiliary wing goes up to meet the outer panel of the upper wing.

What is remarkable in this system of wing construction is that both the stub wing and the auxiliary wings serve a number of purposes. The auxiliary wing serves to brace the upper wing like ordinary struts, but also provides lift. The lower stub wings are even more useful. They provide lift, form conveniently a part of the landing gear structure, and also contain the waterproof metal-lined mail compartments which have a capacity of approximately 60 cubic feet, and which, placed in the stubs, do not encroach on the passenger compartment. The advantages of this peculiar wing system are obvious. The auxiliary wings do not just introduce air resistance when performing their bracing function; they lift and carry load. The stubs carry load, yet they give ideal support to the landing gear. There is a general gain in efficiency.

The landing gear of the *Airbus* also represents a departure from conventional practice. The wheels go into recesses at those ends of the stub wings where the auxiliary wings join. The wheels are cushioned and kept in their proper position by oleo struts; the struts are attached to beams running from front to rear of the landing gear recesses. The wheels disappear almost completely into the stubs, yet at the same time they are well below the fuselage of the plane. This type of landing gear, therefore, attains many of the advantages of the retractable landing gear without its mechanical complication.

The control system introduces a wrinkle, not new perhaps, but interesting. Each aileron is separately connected to the control wheel, so that if one aileron becomes inoperative, there is the other to count upon.

In the passenger cabin, there is another minor yet useful idea. The passenger seats on each side of the cabin are on a platform 12 inches high. This leaves a sunken aisle down the middle, permitting a tall man to stand erect. The baggage is conveniently stored beneath the platforms on which the seats rest.

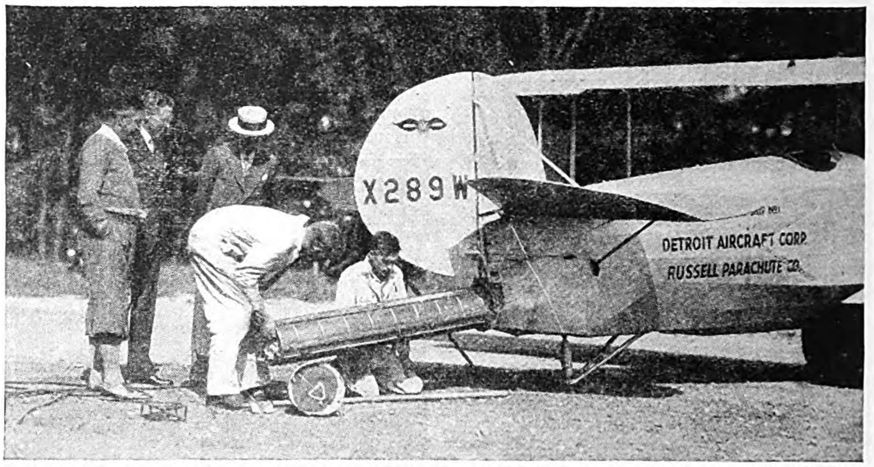
With a Curtiss Conqueror 600 horsepower engine, with 4000 to 4500 useful load —say 10 passengers, 250 pounds of baggage, some 1000 pounds of mail, and 200 gallons of gas—the high speed is 147 miles per hour, the cruising speed 125 miles per hour.—*A. K.*

AN AIRPLANE PARACHUTE

MUCH thought and effort have been expended on the design and use of parachutes for passenger service. Recently we described in these columns a quickly-detachable and attachable parachute for passenger use. There always remains the question, no matter how easy the use of the parachute may be made for the passenger, of whether the average passenger will have the presence of mind to avail himself of this device or whether he will pull the rip cord neither too early nor too late. Many authorities are of the opinion that the better plan is to provide a parachute for the entire plane. The Russell Parachute Company has developed such a "ship parachute," as it is frequently called, and, with the co-operation of the Detroit Aircraft Corporation, has recently tested out the apparatus on a Parks two-seater biplane of about 1800 pounds gross weight.

Aviation describes the apparatus in somewhat greater detail than the reports of the Russell Parachute Company itself:

"Except for a control lever in the cockpit, four suspension cables attached to the plane's center section, and, of course, the control lever cable, the entire device is enclosed in a metal tube, made scarcely noticeable by being faired into the bottom of the fuselage. The tube is about 11 inches in diameter and extends from a point directly below the center section to a point below the rudder hinge line.



Loading the airplane parachute in the tail of the fuselage. The pilot 'chute which is contained in the cup pulls the large 60-foot 'chute from the cylinder

"The 'chute, 60 feet in diameter, is folded inside a metal container, or 'split can' located all the way forward in the tube. The 'can,' which is round, has an inch clearance between it and the inside wall of the tube. Runners inside the tube hold the 'can' in exact center. The four suspension cables extending from the lower shroud lines of the 'chute to the plane's center section are run out of the forward end of the can, through guides located between the can and the inside walls of the tube to a streamlined cap on the after end of the tube. They then extend through an opening in the cap, thence to guides located near the top of the rudder post, after which they are carried to the plane's center section by means of additional guides on the back of the fuselage. Between the streamlined cap and guide atop the rudder post, two cables extend along the two sides of the fuselage to prevent the parachute cables fouling on the tail surfaces.

"The pilot's control cables extend directly from the cockpit to the cone-shaped cap which is attached to an 18-foot pilot or 'drag' 'chute. Operation of the device is as follows: When the pilot lifts his lever in the cockpit, the cone-shaped cap flies off the tube, releasing the drag 'chute. By means of the drag cable, the small 'chute pulls the split can containing the large parachute out of the tube. Upon being released from the tube the split can opens and releases the large 'chute, which pulls the cables from their guides, thereby suspending the plane from its center section by means of the four suspension cables."

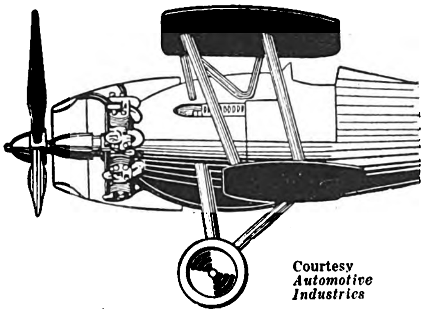
The whole apparatus weighs only 100 pounds, and it is claimed that it will right the airplane from any difficult position and bring it down at a speed of 16 feet a second, which will mean a rough but perfectly safe landing.

On the first test, the Parks biplane landed in a tree under conditions approximating those that would be encountered during emergency use. The only damage sustained was a broken propeller and a bent axle. Further tests will be awaited with interest.—*A. K.*

COWLING-IN THE RADIAL ENGINE

THE great objection to the radial air-cooled engine is that the projecting cylinders not only have large resistance themselves, but that they also break up the streamline flow over the fuselage and thereby introduce still more "parasite" resistance.

A. H. R. Fedden in a paper before the Institution of Mechanical Engineers (of England) visualizes a completely cowled-in radial engine, shown diagramatically in the accompanying sketch. The cowling is of streamlined form itself, and blends with the streamline design of the rest of the fuselage. The propeller is of necessity mounted on a shaft extending somewhat farther from the engine than in the conventional type of engine. Through a circular hole at the front end of the cowling only enough air is admitted to cool the motor. The cooling air then passes through a circumferential gap, behind the engine, and at exit combines, with minimum disturbance, with the main flow around the fuselage.



Courtesy *Automotive Industries*

Fedden's conception of a cowled-in, radial, air-cooled engine to correct objectionable features of this type

Certainly such cowling-in should be decidedly beneficial to the over-all performance of the airplane, and we do not see that it offers any insuperable difficulties of a mechanical character.—*A. K.*

FLEXIBLE-WING PLANE

WE append two photographs of the Waterman "fool-proof" plane built in Los Angeles. The complete technical details are not yet available, but the principles of the invention will be deduced from our photographs.

The outer portion of the wings is not rigidly connected to the airplane. It is rather hinged about the wing stubs adjoining the fuselage and controlled by the action of the two struts which can slide in and out of the hydraulic cylinder mounted on each side of the fuselage. By means of this hydraulic adjustment, the dihedral, or V, of the wings can be changed at will and therefore the lateral stability of the plane can be varied to suit flying conditions or the pilot's preference.

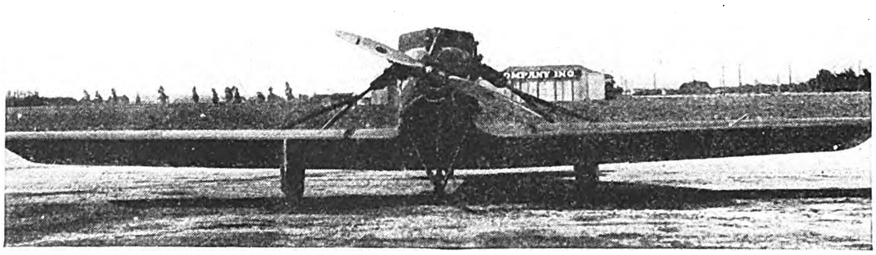
We believe, but we are not quite sure, that when the V is increased, the angle of incidence of the outer portion of the wing is somewhat increased. This means that the wings can be set at the angle most appropriate for high speed, for cruising, or for climbing.

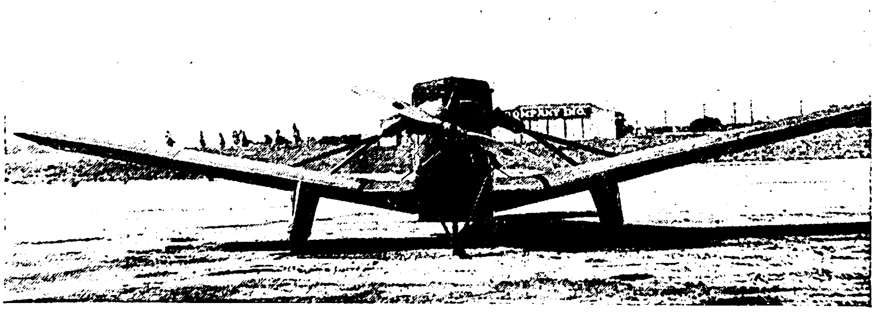
The movement of the piston in the cylinder is controlled by the pilot, but the wings are also slightly automatic in action and therefore respond to gusts striking the airplane. If the wind gust is such as to tend to raise the left wing, then the left wing will yield, thereby decreasing the effect of the gust. If the gust strikes both portions of the wings from below, both wings will yield and the load will be relieved. This might tend to make flying in "bumpy" weather slightly more comfortable. That it will add to the structural strength is doubtful.

When flying, even in rough weather, the loads due to gusts are small in comparison with the loads which the pilot can impose himself in landing the plane; and raising the outer portion of the wings lowers the machine considerably relative to the ground. This brings into play a huge skid at the front end of the machine. The skid grazing the ground acts as a powerful brake and as the center of gravity has been loaded there is no tendency for the plane to turn over on its nose.

Against these theoretical advantages are to be set the complications of the device. Complete theoretical and practical investigation of the device would be necessary before its value could be determined. But Mr. Waterman has flown his craft safely across the continent and back and that is worth considering.—*A. K.*

At right: The Waterman "fool-proof" plane in which the wings yield against the restraint of hydraulic cylinders to give less "bumpiness" in gusty weather. **Below:** The same plane with its wings raised



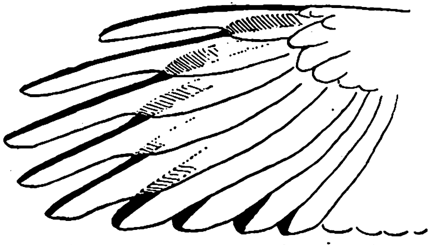


SAFETY DEVICES IN BIRDS' WINGS

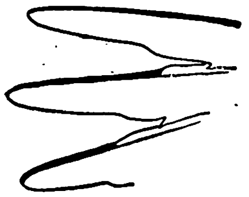
BIRDS are the result of the survival of the fittest through countless ages of flying; we have been flying for only some 27 years. Perhaps we have yet to learn many flying secrets from them. Lieutenant R. R. Graham, writing in a recent issue of *British Birds*, certainly makes a strong case for the possibility of such lessons. (Another exposition on the same subject appeared on page 386, November 1930, *Scientific American*. Editor.)

Nature has provided birds of many species with separating flight feathers. A notable example is the wing of the buzzard, seen from below in one of the appended sketches.

The separating flight feathers of the buzzard present what the ornithologists call "emargination." The separating feather is reduced in width from a broad base to a much narrower tip. The result of this arrangement is that when the wing is fully spread, the outer parts of the feathers do not overlap, and gaps or "slots" form between them as is apparent in the same sketch. The feathers radiate or spread out from a fairly small center. Without this emargination the slots would be narrow at the base. With emargination the slots are of a fair width, even at their inner extremities.



***Above:* The under surface of the right wing tip of a buzzard. *Below:* The lower surface of a song-thrush's right wing-tip, with the slots more than fully opened. Gaps appear beyond inner limits of slots**



The feathers are worth a little further study. In the flight feathers of a partridge not only is there some degree of emargination; there is also more width of web behind than in front of the shaft. In aerodynamical parlance the center of pressure of the feathers is behind the shaft.

The result of this "construction" is that when the flight feathers open, they twist upwards at the rear edge (a fact fully confirmed by actual photographs). The flight feathers then offer a series of fair slots, *with the incidence of the flight feathers smaller than the incidence of the main wing.*

Surely the flight feathers are in close analogy to the Handley Page multi-slot.

When the bird wishes to descend steeply, he sets his main wing to a large angle with the wind. The main wing is "stalled," loses lift, and acts as a brake. The slotted tips are not stalled and still give lift, and hence there is also lateral control still available. In other words the bird is an airplane or glider which can make a steep, stalled descent, with perfect control.

Of course, as Lieutenant Graham points out, the bird has one point of superiority which is difficult for us to imitate. If the stalled descent is too rapid in a vertical direction, there is danger that the bird will strike ground or water too rapidly. He then flaps his wing back and forth and secures lift by a few strokes just before alighting. A mechanical embodiment of this practically horizontal movement of the flight feathers would be very difficult for us to secure.

Among other wonders of bird "construction" described is a very interesting safety device. A bird's wing tip, with feathers loose from one another, can be drawn so far apart in our hands that gaps appear beyond the inner limits of the slots and barbs are torn apart from each other. This is the case for the song-thrush's wing tip. But when an effort is made to spread the feathers while pressed together, it is found that they will open thus far and no farther. Examination of the feather surfaces with a microscope indicates that the effect is brought about by thousands of tiny hooks which stand out above the main surfaces and engage with the ribbed under surface of the broad part of the overlapping feather.

This is certainly a complete vindication of the value of the Handley Page slot, if the birds are to be credited with knowing something about flying!

MAJOR WILLIAM C. OCKER

WE are very pleased to announce that, after proof of the article "Instrument Flying to Combat Fog," on page 430, had been finally okayed, we received word that its author, William C. Ocker, had been promoted from the grade of Captain to that of Major, Air Corps, United States Army. It was too late to make this change under his name in the byline of the article.

Major Ocker's promotion indicates a rendering of recognition for his splendid ability by the Chief of the Air Corps and therefore gives to his article an even greater authoritativeness, if that is possible.

99.99 PERCENT PURE ZINC

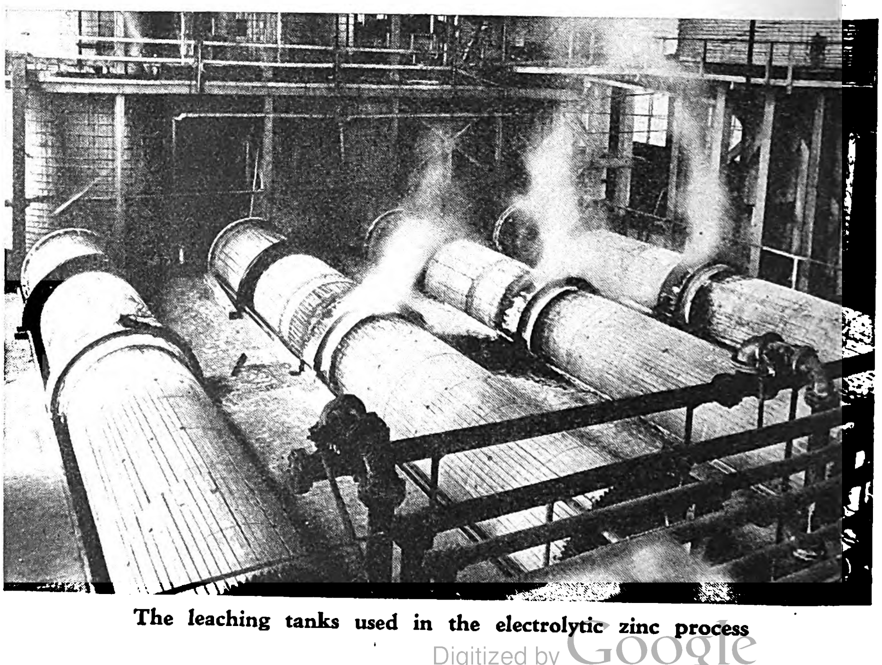
ELECTRO-CHEMISTS of the Evans-Wallower Zinc Company in St. Louis have exceeded the famous record of a well-known soap, advertised as 99.44 percent pure, by developing a process for the production of zinc which is actually 99.99 percent pure. The process is an electrolytic one—the zinc being extracted by dissolving the ore in acid and electrolyzing the resulting solution to extract the pure zinc. Metal of this purity has remarkable properties, being very ductile and possessing high tensile strength. At 350 degrees Centigrade it can be extruded quite readily and drawn into wire.

The process used in this new plant is described by Charles W. Cuno in a recent issue of *Industrial and Engineering Chemistry*. The zinc ore, known as concentrate, contains zinc sulfide and small amounts of cadmium, copper, and iron. The ore is first dried and roasted and then passed through magnetic separators which divide the material into two parts—one high in iron content and the other very low in iron content. The magnetic material which contains the more insoluble zinc is treated with dilute sulfuric acid, in specially designed leaching tanks. The ore is tumbled around in these leachers until the insoluble zinc compounds have been decomposed, after which the non-magnetic portion of the ore is added. During the first stage of the leaching operation, the iron dissolves and is later precipitated as the charge neutralizes the acid. When the leaching operation is complete, the solution and residue are filtered, thus removing the insoluble residue of iron, silica, lead, gold, and silver. The residue is dried and shipped to a lead smelter for the recovery of its metal values.—*A. E. B.*

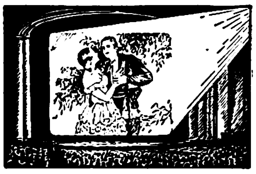
SOUTH CAROLINA VEGETABLES

THE state of South Carolina is taking seriously the question of the mineral content of its vegetables. A foundation has been established with a research laboratory and enough evidence has already been accumulated to arouse propaganda for California packers to move to South Carolina. The California fruit growers have emphasized the importance of California oranges as a source of vitamin C. The South Carolina Food Research Laboratory counters with a comparative statement showing that California oranges provide 70.5 parts per million of iron as contrasted with 160 parts per million in South Carolina tomatoes; they contain 7.6 parts per million of manganese as contrasted with 26.7 parts per million in South Carolina tomatoes and the oranges contain 4.75 parts per million of copper with 15.3 in tomatoes. Little has been claimed for California oranges so far as concerns their iodine content, but the South Carolina tomatoes contain 166.5 parts per million of this valuable mineral.

The South Carolina authorities, led by Dr. William Weston, recommend South Carolina tomato juice as superior to California orange juice for the growing infant. In their experiments on the feeding of infants, the South Carolina Food Research Laboratory has emphasized particularly



The leaching tanks used in the electrolytic zinc process



heroes must not lisp!

"My thweet" lisped from the screen would mar the star's romantic appeal. But that is something you don't hear in the theatres which have Western Electric talking picture equipment.

To reproduce the letter 'S' was but one of many difficulties in the way of giving you talking pictures at their best. Western Electric was able to solve these problems by reason of its 50 years' experience in making Bell telephones and other voice transmission apparatus.

All over this country, and indeed the world, a discriminating public flocks to Western Electric equipped theatres—one more proof of this company's leadership in *sound.*

The blue annealed sheet-iron section of the base for the new experimental iron base highway. The middle cut shows the section where corrugated iron was used as the base, corrugations running parallel to the road. *At bottom:* Brick surface was laid according to regular practice. The road was finished after the accompanying article was written

the value of carrot top and lettuce concentrates. These seem to be especially valuable as a source of iodine, manganese, iron, and copper.

The relationship of manganese, copper, and iron to anemia has already been emphasized in many publications. Much has been written of the value of liver in control of anemia. The South Carolina authorities urge oysters as of interest in this connection.—*M. F.*

◆

TRANSPACIFIC SPEED RECORD

A THIRD record was shattered when the Canadian Pacific liner *Empress of Japan*, completing her first voyage from Japan to Canada, docked from Vancouver, Victoria, and Honolulu at Yokohama recently. The elapsed time for the trip from Honolulu to Yokohama was 6 days, 19 hours, 43 minutes, or about 20 hours faster than the previous record held by the N.Y.K. liner *Chichibu Maru*.

During her Pacific lifetime of only a few months, the new Canadian Pacific liner has broken the record for each leg of the voyage.

IRON BASE FOR EXPERIMENTAL HIGHWAY

A CONTRACT for an experimental pavement with an iron base and curb has been placed for 150 feet of pavement, on the Grand Avenue Connection, near Springfield, Illinois, with the Rochester road, (State Highway, Sagamon county.) The roadway to be laid this month will be the first test of three different designs. The iron base and curb will be laid on a levelled highway, says a report which discusses the design of this highway, which may revolutionize the building of roadways.

As explained by the engineers, the road will have a carefully rolled and prepared sub-grade on which the iron base and curb will be laid. Next will follow a mastic sand cushion upon which will be placed a layer of two and one half inch or three inch brick with asphaltic filler poured into the interstices between the bricks. The result, it is declared, will be an indestructible base with a smooth riding surface built into the structure with sufficient flexibility to meet temperature changes without breaks or cracks.

The iron base will consist of three 50-foot sections. One will be blue annealed flat sheets and the other two galvanized and corrugated sheets. The corrugations in one 50-foot section will be parallel to the road and in the other they will be transverse. The flat iron base will be ¼ inch thick, and the corrugated galvanized will be 10 gage.

The three types mentioned above will be tested under actual conditions. If they prove successful under traffic conditions, great progress will have been made in highway construction, is the belief of engineers. Such a roadway will not only be flexible, but should eliminate cracking and permanent deformation. The use of rust-resisting materials will insure durability. The iron base is Armco Ingot Iron and will be rolled and fabricated by The American Rolling Mill Company and the brick will be furnished by the Poston-Springfield Brick Company, of Springfield, Illinois. The National Paving Brick Manufacturers Association is co-operating in the test.

Mr. Mosely, the originator of the idea, recognizes that the success of the new metal highway depends to a large extent on the longevity of the metal used.

◆

CRYSTALLINE RUBBER CLEAR AS GLASS

CRUDE and refined rubber are known to consist principally of hydrocarbons. These hydrocarbons are mixed with smaller quantities of various impurities which can be removed only by a series of long and tedious operations. The highly purified rubber resulting from these operations is a clear, colorless, transparent, elastic solid, as clear and colorless, in fact, as the best plate glass. The problem of ascertaining the composition of this highly purified rubber has heretofore been exceedingly difficult because of the fact that two of the most useful processes ordinarily employed by the chemist—crystallization and distillation—could not be applied to the material.

A process has recently been developed at the United States Bureau of Standards by which this pure rubber can be repeatedly crystallized, thus opening the possibility of successfully fractionating it into its constituent hydrocarbons and eventually of determining the formulas of their molecules. The crystalline rubber obtained by this process, as seen under the microscope,

Actual PUMP INSPECTION *Safeguards* ETHYL quality

ETHYL
BRAND OF ANTI-KNOCK COMPOUND

Ethyl inspector purchasing actual sample of Ethyl Gasoline *from the pump*. In Ethyl laboratories this sample must meet all Ethyl requirements.

MAYBE you've seen these inspectors, driving cars like this, stopping at Ethyl pumps, buying a gallon here and a gallon there. They are Ethyl representatives—making sure that all gasoline sold under the Ethyl emblem has the full extra quality of Ethyl Gasoline.

Each one of these cans is sealed and marked at the filling station and sent to Ethyl laboratories for testing.

The 76 oil refining companies that mix Ethyl fluid with their gasoline cooperate by authorizing these tests so all Ethyl Gasoline will meet the standard you have learned to expect.

Before any gasoline is mixed with Ethyl fluid at the refineries, a sample is sent to an Ethyl laboratory. A test shows how much Ethyl fluid is needed to bring it up to the standard of Ethyl Gasoline. At least this much Ethyl fluid is then added. After the mixing, a sample of the finished Ethyl Gasoline is sent for testing.

But even this is not enough. To make sure Ethyl Gasoline reaches you with quality unchanged, inspectors take samples from Ethyl pumps throughout the country.

So you are triply protected when you buy at the pump that bears the Ethyl emblem. Its standard of quality is never lowered. Ethyl Gasoline Corporation, Chrysler Building, New York City.

ETHYL GASOLINE

Ice in the ship channel of a river "rotted" away and a clear channel being made with calcium chloride

consists of small transparent plates. As the crystallization process continues, these plates agglomerate into larger and larger clusters. The crystallization process is carried out by cooling a dilute solution of the highly purified rubber dissolved in ether to a temperature of about –80 degrees Centigrade.—*A. E. B.*

DESTROYING CHANNEL ICE

LAST winter a steamer loaded with valuable cargo was imprisoned in the ice of Lake La Barge near the headwaters of the Yukon River. With buckets and brooms the crew swabbed a strip, 29 miles long and 40 feet wide, of lamp-black and thinned refuse oil across the ice. And because black absorbs the sun's rays and retains heat, this strip in the course of a month cut a channel a foot deep as evenly as though it had been sawed. It continued to deepen and widen so that the boat was released from the ice one month ahead of its usual time.

At Morrisburg, Ontario, a steam ferry operated all last winter on schedule through a channel kept open with the aid of calcium chloride.

Here are typical examples of the results obtained by Dr. Howard T. Barnes, of McGill University, who is acknowledged as the world's leading exponent of the new science of ice engineering. He has discovered that calcium carbide, calcium chloride, sodium chloride, charcoal, lamp-black, and cinders will "speed up" the spring thaw of river, lake, and harbor by as much as one month. These materials "rot" and destroy surface ice in the most frigid temperatures, leaving it weakened to such an extent that when the sun swings northward in the spring, the ice melts quickly along these lines of least resistance and passes down stream in small cakes. By spreading these chemicals in a definite pattern over the ice with the aid of an ordinary road-spreader, young ice has been destroyed in a few minutes and channels kept open in proportion to the economic desirability of such work.

Dr. Barnes has also developed two very powerful weapons against icebergs and ice jams. One of these is thermit, which was first described in the press several years ago. Placed in shallow holes dug in the ice at strategic points, it is touched off either with a fuse or a small charge of flashlight powder. The iron oxide and aluminum powder, of which it is composed, instantly react by producing a temperature of 5000 degrees while streams of molten steel are shot through the ice in all directions. The surrounding ice is literally decomposed into its constituent elements of hydrogen and oxygen, the former being released as a flaming gas which often flares a hundred or more feet into the air.

By this means Dr. Barnes destroyed an immense ice jam in the St. Lawrence River which weighed more than 1,000,000 tons, only two 90-pound charges being employed. On another occasion he vanquished an iceberg which measured 500 feet at the water line with a single charge of 100 pounds.

Last winter the ice engineer perfected a new weapon called solite. It is equally as powerful as thermit, but needs neither fuse nor battery to touch it off. Loaded into bombs it can be dropped on otherwise inaccessible icebergs from speeding planes with no risk to the operator. The bombs are open at the top, and as they rush through broken ice a partial vacuum is formed in the hole which prevents the water from entering. When the bomb finally comes to rest the water rushes into the hole and automatically ignites the charge. Experiments conducted on the St. Lawrence River last winter and by the International Ice Patrol off the coast of Labrador last spring prove that solite is eminently successful in destroying both ice jams and icebergs.

BUTYL ALCOHOL FROM POTATO PULP

WASTE pulp from potato-flour factories will be used as a raw material for the bacteriological production of butyl alcohol and acetone by a process developed at the Dutch agricultural experiment station at Gronigen, according to a report from the commercial attaché at The Hague. The process is said to overcome the difficulties caused by the varying composition of the pulp and its usually strongly soured condition. Millions of pounds of pulp are available annually, and production using this patented process will be begun as soon as possible.—*A. E. B.*

THE STING OF THE HONEY BEE

THE sting of the honey bee is seldom considered to be of much importance, except when an entire swarm attacks a man; then he is likely to suffer greatly from manifestations of his disturbance. When a person is stung by a bee it is customary usually to apply solution of ammonia or of baking soda to the skin. Ordinarily this is sufficient to modify the local irritation, and little more is thought of the trouble.

Some studies recently completed in the Mayo Foundation indicate that the venom of the honey bee resembles that of the rattlesnake in several particulars. Both poisons when in contact with the blood break down the red blood cells; both poisons when injected into the arm promptly stop its action. Bee-sting poison is a stimulant of smooth muscle, such as is found in the heart and in the uterus and is a dangerous poison to the lining of the blood vessels. Obviously it is a potent substance and if taken into the body in sufficient quantity can produce death as can the venom of the rattlesnake.—*M. F.*

CAR SICKNESS

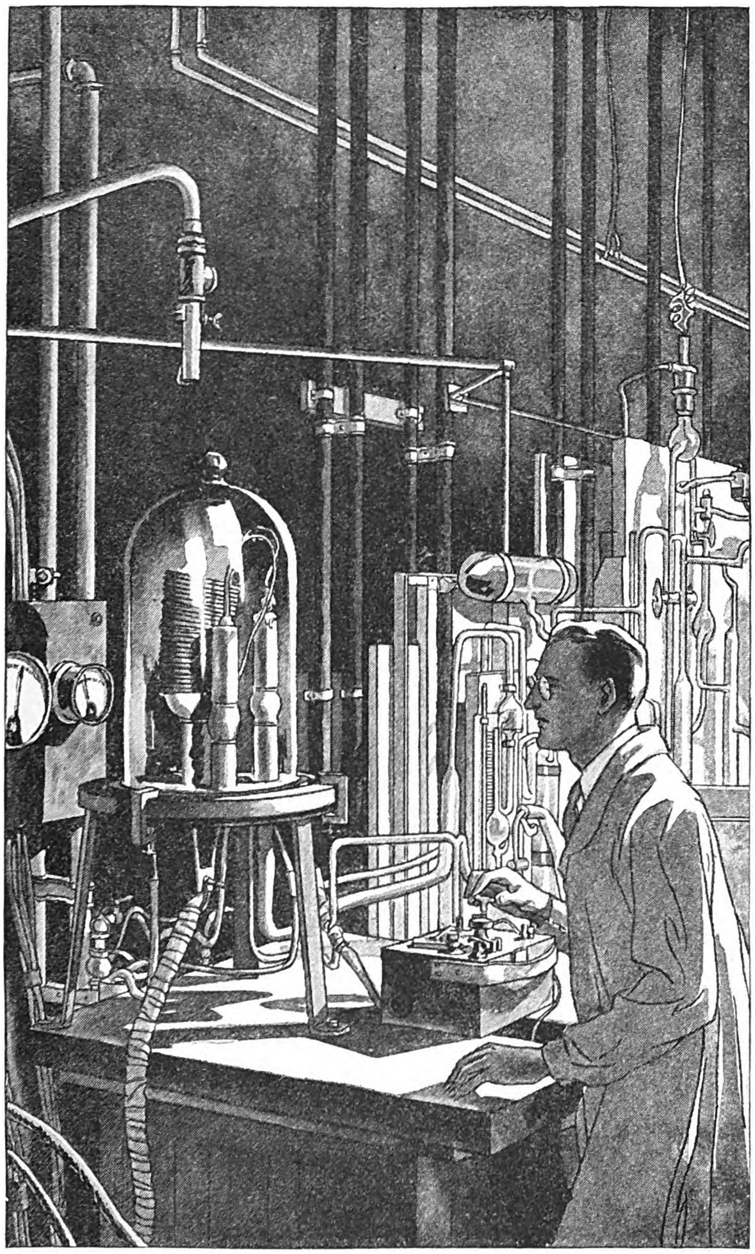
MANY people experience great discomfort when riding in trains or street cars. Many more become dizzy and uncomfortable in ships or airplanes. Physicians who have studied the subject are inclined to place the responsibility on the mechanism of the internal ear and on the eye. The tendency to car sickness seems to run in families. Dr. James E. Lebensohn points out that people most frequently disturbed usually avoid riding backward and favor the front seat of the automobile, where there is less jarring and where the view is less constricted. He points out also that when the land traveler gazes at the scenery, his eyes slowly follow the objects in the landscape which appear to be moving backward. As these objects pass out of the range of the vision, the eyes return to their normal position. Hence the eyes are constantly jerking, and this causes many to believe that the eyes are responsible for railroad sickness.

The chief symptoms of nausea are paleness, sweating, and goose flesh, most of these things being associated with nausea no matter how it is produced. In making a special study of the relationship of the eyes to car sickness, Doctor Lebensohn produced the jerking of the eyes that has been mentioned, known as optical nystagmus, and at the same time studied the changes that took place in the stomach. A cylinder marked in black and white was revolved before the patient's eyes to produce ocular nystagmus and cold water was thrown into the ear to produce labyrinth or internal ear nystagmus. At the same time the contractions of the empty stomach were measured by the movements of an instrument connected with a balloon swallowed and retained in the stomach.

Destroying an ice jam with 12 pounds of solite, the new chemical which is "touched off" by water

ECONOMICS OF THE ELECTRICAL INDUSTRY

TOMORROW'S COST PROBLEMS...



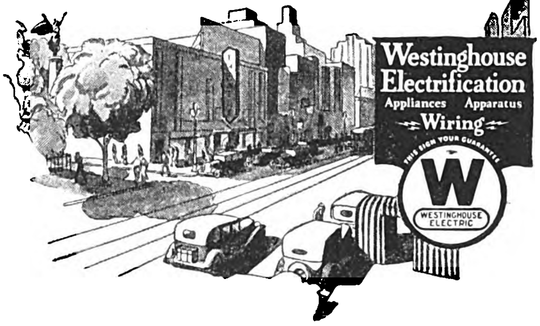
...in Today's LABORATORIES

Modern science may well smile at the medieval alchemist, calling vainly upon the powers of darkness to aid him in transmuting base metal to gold. The workers in today's research laboratories call upon the powers of electricity — and secrets of far greater value are their almost daily reward.

It is impossible to estimate the vast increase to the world's wealth that electrical research has brought. In the Westinghouse laboratories at East Pittsburgh alone, discoveries valued well into the billions have been made. A cost-saving contribution to a single industry may be worth millions. A new metal to cut down transformer losses, a De-ion circuit breaker that eliminates oil quenching and consequent fire hazard, a marvelous "electric eye" that performs all manner of human tasks — and never forgets; these modern Westinghouse developments are part of the day's work typical of an organization devoted to enlarging the service of electricity in every field of modern life.

Tune in the Westinghouse Salute over WJZ and the coast-to-coast network, every Tuesday evening.

Westinghouse



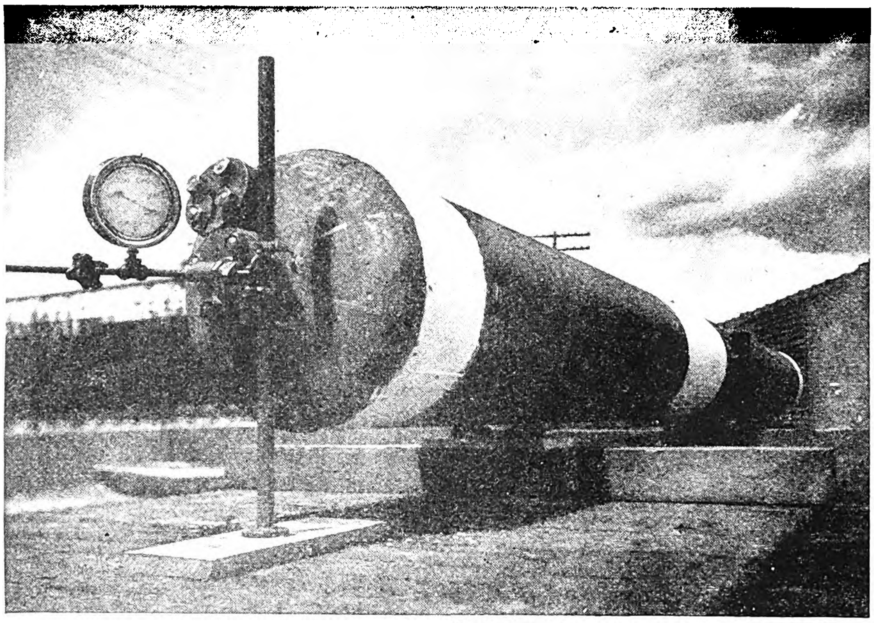
It was found that the effects on the eye produced little if any response in the stomach concerned with the maximum contractions associated with the production of labyrinth nystagmus. Hence Lebensohn is convinced that car sickness is due to the irritation of the mechanism in the internal ear, but he feels also that errors of refraction in the eyes and of muscle balance predispose a person to this malady. Such errors act as a depressant to the activity of the stomach and people with disturbances of vision are likely to have a lower resistance to nausea than those free from such disturbances.

The development of smoother roads and easier riding in automobiles is making car sickness less common. Dr. Lebensohn states that it is best not to go hungry when traveling, as an empty stomach is particularly sensitive to depressing influences. He recommends also that errors of refraction and of muscle imbalance should be corrected.—*M. F.*

HIGH PRESSURE TECHNOLOGY REQUIRES POWERFUL APPARATUS

PROBABLY the most lively topics of discussion among present-day chemical engineers are the several new processes in synthetic chemistry which utilize high pressures and high temperatures. By employing pressures and temperatures heretofore deemed impractical, the chemist has developed commercial processes for the fixation of atmospheric nitrogen, the hydrogenation of oil, and the synthesis of methyl alcohol. From the theoretical standpoint, there is nothing particularly new about these developments but it is only within the last few years that equipment suitable for the severe service required by the new technology has become available. New alloy steels of extremely high tensile strength and corrosion-resisting properties have been developed to meet the demands of high pressure technology. It has also been discovered that welded joints in steel pipes and tanks can be made sufficiently strong to withstand the severe conditions imposed.

What is said to be the most severe test to which a welded container has ever been subjected was performed recently on a welded tank by the A. O. Smith Corporation of Milwaukee, Wisconsin. One of our photographs shows the tank, which is 33 feet long, with 3½-inch walls, and an inside diameter of 26 inches, being subjected to a pressure of 10,000 pounds per square inch without any sign of failure.—*A. E. B.*



Welded reaction chamber for a new synthetic process, being tested at the high pressure of 10,000 pounds per square inch without a sign of failure. The working pressure which this cylinder must withstand when in operation is 500 pounds

QUICK-FREEZING CANNED FRESH PEACHES

WHAT promises to be the first step in the establishment of an important new food industry has just been completed by Tom Huston of Columbus, Georgia, already widely known as "The Peanut King" and as an outstanding example of the South's younger generation of business leaders. While other organizations and individuals throughout the country have been experimenting, without notable success, in the application of the quick-freezing process to fresh fruits, Mr. Huston has organized Tom Huston Frozen Foods, Inc., built a 100,000-dollar plant at Montezuma, Georgia, the first of its kind in the world, and has completed a successful season of freezing fresh, tree-ripened Georgia peaches in commercial quantities.

Although for some years it has been a fairly common practice in the Pacific Northwest to freeze strawberries and a few other berries grown in that area, these products have been prepared for use chiefly by ice cream manufacturers, confectioners, and bakers. The Georgia plant represents the first step toward placing frozen fresh fruits on the market for family consumption, and for the entire year round. As such it is of outstanding importance to both consumer and grower, promising the former a new line of healthful and appetizing food products, and the latter a broader, more profitable, and better stabilized market.

Essentially, the process is the same as that which has recently been applied to the quick-freezing of fresh meats. By this method it is possible to imprison the original flavor in the fruit without that breaking down of the cells which accompanies ordinary freezing—a more difficult problem in the case of fruits than meats, since the cells are more delicate. The peaches are allowed to ripen on the trees. They are frozen within a few hours of reaching the plant, which is in the heart of the Georgia peach belt. Thus they have an opportunity to reach their full perfection of flavor, and no opportunity to lose any of it during transportation or while in storage.

Practically all of the fruit is brought from within a radius of about 15 miles of Montezuma. The fuzz and skin are first removed by a special process, after which a belt conveyor carries the peaches to tables where they are split in half, pitted, and carefully inspected. They are then run through slicing machines and down a belt conveyor to other tables where the slices are packed in quarter-pound containers, and a little sugar syrup is added. The containers are capped by machine and then pass through the freezing tunnels where the temperature is 35 degrees below zero. The entire process is completed under the most rigorously sanitary conditions.

The filled containers are kept in a cold

Georgia peaches, to be frozen in the cartons on the conveyor in front of the girl workers, have a sugar syrup added to them from the rubber hose overhead

Arctic clothing in Georgia! In the cold rooms where peaches are preserved by the quick-freezing method, the workmen have to be so clothed against the intense cold

room until ready for shipment. To maintain the necessary degree of cold, they are passed to the refrigerator cars through a portable, insulated tunnel. In the warehouse, hotel, restaurant, club, or drug store they are kept constantly at low temperature.

THE CONSTITUTION AND GASTRO-INTESTINAL DISEASE

IN the beginning of modern medicine, that is to say at the time when Hippocrates first introduced accurate observation as the basis of scientific study, attention was paid to the constitution of the human being and his structure in relationship to the disorders from which he might be likely to suffer. Indeed, the Greek teachers classified human types according to various characteristics. Persons of certain types, they asserted, were likely to suffer with certain diseases. The conception was favorably received and guided medicine until approximately the 13th Century, when the beginnings of modern research focused attention not so much on the human being as a whole as on individual tissues and structures and disorders. In more recent years it has come to be realized that medicine must be much more concerned with the human being as a whole. It is recognized that heredity and constitution are of vital importance in understanding the nature of man.

In his chairman's address before the section on diseases of the stomach and intestines at the last annual session of the American Medical Association in Detroit, Dr. Julius Friedenwald gave special attention to the human constitution in its relationship to gastro-intestinal disorders. He called attention to the fact that workers throughout the world are now concerning themselves with this point of view. He mentioned particularly the work of George Draper and his constitutional clinic at the Presbyterian Hospital in New York and the work carried out by Raymond Pearl and his co-workers in the division of human genetics in the constitutional clinic in Johns Hopkins Hospital. Individuals have been measured with relation to the

Masterpieces of Brilliant Merrymaking

THE BEST WIT, WISDOM, AND SATIRE IN OUR LANGUAGE

HERE ARE the pithy and humorous folk tales, the fantastic themes, the light verse, the brightly comic narratives, which have helped to keep the world young since the dawn of literature. Here are the neatly pointed epigrams, the brilliant repartee, the keen satire, the sparkling wit, the profound wisdom, which have helped to make the world wise.

It is without exception the most complete, authoritative, attractive, interesting and useful collection of the most brilliant and classic literature in the English language.

A GIFT TO REVIEW OF REVIEWS READERS

A WHOLE NEW EDITION, beautifully bound and printed, has been made and reserved for new and old friends of the Review of Reviews. Do not mistake these books for the usual small, flimsy, poorly made gift books—they are real books bound in handsome red cloth, portrait frontispiece in each, 300 pages, good paper—the kind of books you will be proud to place on your bookshelf. This set is yours absolutely free with a three-year subscription to the magazine, at a special reduced price. And, what is more, this may be paid for in small monthly instalments if more convenient. This is your special opportunity to become a subscriber, or if you are already one, this offer is good on an extension of your subscription. Or why not send Review of Reviews to a friend as a gift? Everyone needs a reliable news magazine these days.

THE REVIEW OF REVIEWS

You get the essential news quickly and accurately, intimately and in satisfying doses in this monthly news magazine. Not only do you miss nothing but you are told what it is all about by men who speak with authority. The gossip is omitted, the facts are made interesting so that regular readers are a little better informed than their neighbors and competitors. National affairs, political trends, social problems, foreign relations, business, finance, education, science, travel, and sketches of people of importance are collected from authoritative sources by experts—the outstanding articles from other magazines condensed so that you have many magazines in one. This news magazine is like a monthly chat with an old friend who knows all about everything and is not tiresome about telling it.

10 Days' FREE Examination

Send no money now. Just sign and send the coupon today. Your first number of the magazine and the 9 free volumes will be sent to you for 10 days' examination without cost. Then if you are pleased the special three year subscription price may be paid in instalments of $1.00 each. Otherwise, return the books in 10 days at our expense.

REVIEW OF REVIEWS CORP. S.A. 12-30
55 Fifth Ave., New York City

Send me the 9 volume gift set of WIT AND HUMOR and enter my name for a three year subscription to the Review of Reviews. After 10 days, if pleased, I will send you $1.00 a month for only 8 months. Otherwise, I will return the books at your expense.

Where glass is spun into fine "wool"

various diseases from which they have suffered, the records of their ancestors have been investigated, and it is now realized that the heredity and the constitution of the individual are of utmost importance in the diagnosis and treatment of disease. The mouth may contain extra teeth or be deficient, the palate may fail to close and there may be hare-lip. Tongue-tie may be manifested through several generations. Various forms of indigestion have been associated with certain temperaments. Hypertonus of the stomach is associated with hyperacidity and lower tonus of the stomach is associated with lessened acidity.

Individuals of the heavy athletic type with short chests and long abdomens are likely to have stomachs of increased tonus with the digestive organs high in the abdomen. The individual of frail physique with long chest and a short abdomen is likely to have a poor tone to the stomach and the stomach and intestines will be found low in the abdomen.

Draper found that people with narrow facial angles and forward slanting teeth were likely to have the navel in a lower location than normal, and were likely to be sufferers from ulcer of the stomach. People with gall-bladder irritations were of a steady and more continuous form of behavior, whereas those with ulcer of the stomach were unstable and react quickly to their environment.

Cancer of the gastro-intestinal tract has been shown by Professor Maud Slye to be inherited through many generations of mice, and she has shown the possibility of breeding cancer out of the group as well as breeding it in.

The greatest study of mankind is man, and it is important to realize that it is man as a whole that must be studied as well as the individual features.—*M. F.*

UNIQUE PLANT PRODUCES GLASS WOOL FOR STORAGE BATTERY PLATES

PRIOR to the World War, glass wool was imported almost entirely from Germany for the few specialized uses to which it was put in this country. At that time it was known best in the form of ink erasers and was also utilized somewhat in chemical laboratories as a filtering medium. About ten years ago a demand arose for glass wool on the part of storage battery manufacturers. Accordingly, a plant was built in Millville, N. J., in the heart of a glass producing region, for the manufacture of glass wool. This plant, the only one producing this material in the United States, was described in a recent issue of *Chemical and Metallurgical Engineering*.

Fundamentally, the process of manufacturing glass wool is simply that of heating a glass rod to the softening temperature and then drawing it out into a fine thread. While in slow rotation, the glass rod, which is about three-fourths of an inch in diameter, is constantly heated and softened at its extremity by a small, regulated gas flame. When the glass tip has reached the proper initial softness, an operator touches it with a cold rod and, having accumulated a small "gob" of molten glass, carries it about 15 feet to the top of a large rotating wheel and releases it there. The wheel takes charge from then on; the strand that has been pulled over this distance remains unbroken and is wound on the wheel.

In this unique plant of Friedrich and Dimmock, there are 12 batteries of glass rods and wheels installed. Within 3000 square feet of floor space, some 500 pounds of glass wool are produced daily.

The rod holders operating from one main shaft are mounted on a special iron structure. At one end the 12 horizontal rods are inserted in the centers of individual interlocking gears arranged in a vertical zigzag fashion; these gears transmit the desirable slow rotation. At the other end the rods project through and rest on holes in a vertical panel, which gradually retreats to the stationary end as the rods are used up. On the edge of this panel is fastened a narrow gas pipe, having 12 small jets which melt the protruding glass rods and follow them to their disappearance.

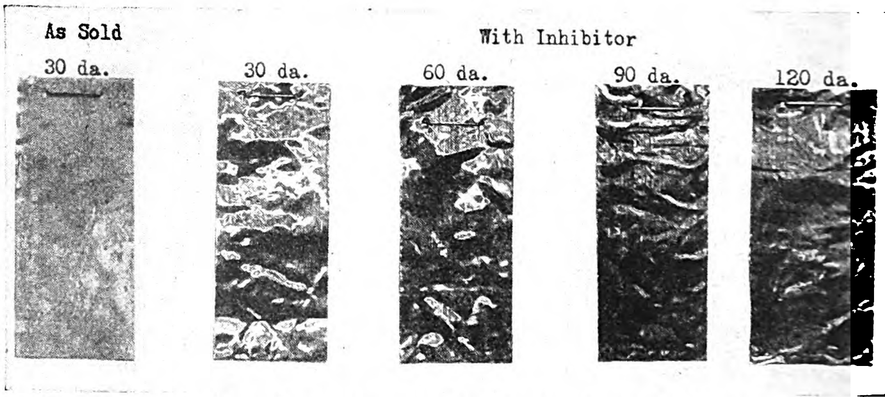
The noteworthy characteristic of this arrangement, shown in the illustration, is its automatic and inevitable synchronism. Once the operator has strung the 12 strands of each battery over their common wheel—a matter of a very few minutes—nothing further need be done until the rods have run out. That is to say, with a given motor speed, the gears will rotate the rods, the gas flame will melt the glass, and the winding wheel will draw the strands, all in a fixed correlation that will give a definite strand size. Thus, if the motor is slowed down, the whole process must adjust itself to produce a heavier strand. What may appear unusual, finally, is that no breakage of the thin glass strands occurs as they traverse the 15 feet of space between units.

The glass wool is finally stripped from the collecting wheels and either shipped in hanks or fabricated into battery insulating plates within the plant. The latter are made from uniform layers of wool that have been dipped in glue and dried in a convection chamber. They are shipped as porous plates with firm smooth sides. Glass wool is also used in filters and light diffusers, and recently as insulation for mechanical refrigerators.—*A. E. B.*

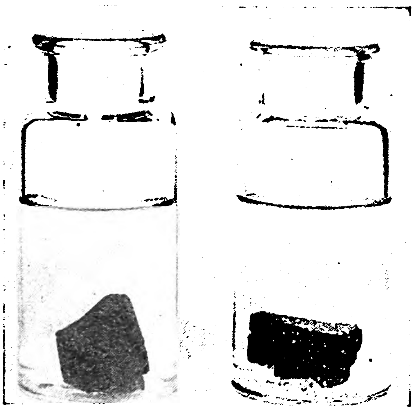
SODIUM SILICATE INHIBITS CORROSION

MANUFACTURERS of shaving soap and cosmetics are increasingly favorable to the use of collapsible tubes as containers for their products. However, one great technical difficulty has militated against the use of this convenient package —namely, the inevitable corrosion of the aluminum tube. Ordinary shaving creams with a soap base, and various alkaline cosmetics, will attack an aluminum tube and in many cases cause its failure within a few weeks, at temperatures well within the range of atmospheric exposures.

Mr. James G. Vail, Vice-President of the Philadelphia Quartz Company, writing in



Test sections cut from shaving cream tubes. The sample at the left shows a dull corroded surface after 30 days. The others show the brilliant surface of aluminum after several months when sodium silicate is used in cream as an inhibitor a recent issue of *Industrial and Engineering Chemistry* announces the discovery that the addition of less than 0.5 percent of sodium silicate to the soap will stop this corrosive action so completely that the metal remains bright after many months. Sodium silicate used for this purpose is known as an inhibitor and its effectiveness as a corrosion resister is clearly demonstrated in an accompanying photograph. The effect of much larger silicate additions than are needed to stop corrosion has been tested by supplying them for regular use to men who did not know their composition. Some noticed more abundant lather but no unfavorable criticism developed.



Effect of silicate treatment on brick exposed to sulfuric acid. The sample at the left was treated before immersion. That at the right was immersed without treatment. Note the deposit of decomposed brick that has settled to the bottom of the solution in the bottle at right

Another inhibiting effect of sodium silicate which is not yet thoroughly understood, is its power to impart resistance to acid corrosion to such materials as Portland cement or ordinary red brick. The surface of the cement or brick is coated with a dilute solution of sodium silicate which penetrates the pores and results in increased resistance to corrosion, abrasion, and penetration of oil and water.—*A. E. B.*

EAR-PHONE DERMATITIS

As more and more strange chemical substances come into industry, new cases of inflammation of the skin due to special sensitivity are reported. When Mah-Jongg became the popular American craze, innumerable cases of sensitivity to the Japanese lacquer used on the Mah-Jongg boxes or tiles were reported in medical literature. A few years ago specialists in diseases of the skin became aroused over the number of cases of people sensitive to the ink used in rotogravure sections of the newspapers.

Now Dr. J. J. Eller of New York reports the case of a man who had inflammation of the skin over both ears and covering the skin just in front of the ears. The patient had used radio ear-phones for two hours, following which his ears itched and burned and became slightly swollen. After several weeks the swelling gradually increased so that eventually both ears became twice their normal size and then the condition gradually subsided. Similar cases have been reported by other physicians.

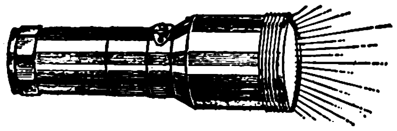
The most precious gift of all

Leica REG U.S.PAT.OFF —the universal camera

JUDGED by its size alone Leica is unique. Judged by its mechanical and optical precision it is the most remarkable photographic instrument of all time. Leica fits the vest pocket and takes 36 pictures on a roll of cinema film, double frame size. And, if you want enlargements, Leica pictures reproduce beautifully to 12 x 18 inches or more. See it at your dealer's—or write for pamphlet 1175. E. Leitz, Inc., Dept. 12 S. A., 60 East 10th Street, New York, N. Y.

1 Fits the vest pocket or woman's purse.
2 Weighs less than a pound.
3 Equipped with Elmar Anastigmat F 3.5 lens.
4 Focal plane shutter with speeds of 1/20 to 1/500 of a second.
5 36 pictures on a roll of cinema film, double frame size.
6 Beautifully clear and distinct enlargements to 12 x 18 inches or more.



NO-BATTERY TORCH

A mechanical flashlight requiring No Batteries. Winding the handle gives a continuous light anytime—anywhere. Not affected by moisture, heat or cold. An extra bulb is carried under the head light for emergency. Blue, red or gray metal case, 8½ inches long. Guaranteed. $10.00. Post paid.

THE AMATEUR ASTRONOMER

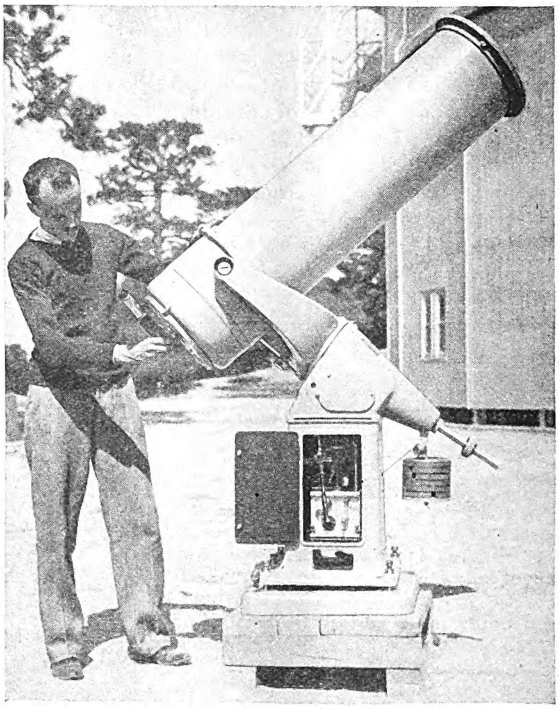
Conducted by ALBERT G. INGALLS

IN the October number, page 320, we reproduced a photograph of one of the four-inch refractors especially designed for the study of various proposed sites for the 200-inch telescope. We now show a photograph of one of two 12-inch Cassegrainian reflectors designed by Russell W. Porter, and approved by Dr. John A. Anderson in charge of the site investigation, for the same purpose. The photograph was sent us by Mr. Joseph O. Hickox of Mount Wilson Observatory. Accompanying it is the following comment:

"Several 12-inch reflecting telescopes have been made for the California Institute of Technology for the purpose of testing seeing conditions at the various sites being investigated for the location of the 200-inch telescope now in course of construction.

"The Pyrex mirrors for the 12-inch reflectors were figured in the optical shop of the Mount Wilson Observatory at Pasadena. The primary focus is five feet, but a Cassegrain focus is available which gives an equivalent focus of 20 feet. Eyepieces of 60, 320, and 480 power are used, the 'seeing' being judged by observing the separate of double stars, the diffraction pattern around stars, and the quality of the detail seen on the moon and planets.

"The mounting is of duralumin, the weight of the complete telescope being 235 pounds. It is provided with reading circles and slow-motion adjustments for right ascension and declination, and is driven by a clock actuated by a weight."



Cassegrainian for 200-inch site investigation

The photograph reproduced was shown to Russell W. Porter, designer of the telescope, who was induced to dictate the following additional comment: "The specifications laid down for this particular mounting were that it should be very rugged and stand rough treatment, as it was intended to be transferred from one site to another on the backs of pack mules or men, and to be easily separated into convenient units for .packing. These considerations made it desirable that all delicate parts be enclosed, as far as possible.

"The entire mounting is of duralumin castings; the tube is of sheet aluminum; the worm gear and adjusting screws of bronze. The only steel in the mounting is the lower bearing of the polar axis and the declination studs. These are chromium plated. The clock weights will drive the clock for 40 minutes before rewinding. The yoke, which is hollow, is especially rugged, and the declination arm and tangent screw are inside one of the arms. A slip ring at the upper end of the polar axis is divided into hour angles, allowing quick setting on any star in right ascension. Hand control in right ascension is by a removable key which engages the worm, whose end can be seen in the little hole on the base casting, just below the yoke.

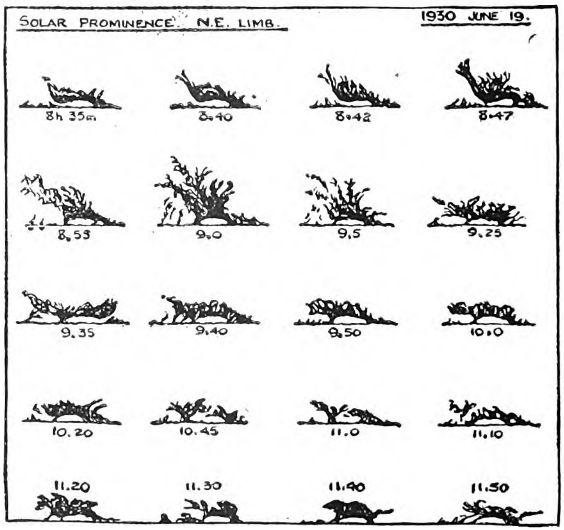
"The cell holding the 12-inch primary mirror is fastened to the casting at the lower end of the tube by a threaded joint making about a half turn. This is not visible on the photograph but lies about halfway between the declination stud and the bottom of the cell. This method of attachment allows the mirror to be removed for safe keeping and to go back again to a positive stop, thus preserving the alignment.

"The whole instrument was painted a light gray with a dull finish and worked down to a beautiful white finish.

"The two telescopes were made by Fred G. Henson of Pasadena. Preliminary tests of the instruments on close doubles showed that the optical surfaces exhausted the resolving power."

THE number of spectroheliosccopes attempted thus far is disappointing. Perhaps the insertion of the series of sketches shown on this page, which gives a concrete idea of what the amateur may expect to see with a spectrohelioscope, may serve to arouse further interest. These sketches were drawn from a solar prominence observed during the morning hours of June 19, 1930 by F. J. Sellers, F. R. A. S., and are reproduced from the *Journal of the British Astronomical Association.* Mr. Sellers points out that this prominence was not a large one, as prominences go, though it was very active. At 9 o'clock A.M. it had reached a height of about 30,000 miles, having risen at the rate of about 12 miles a second.

Seen through the spectrohelioscope these prominences are red and are a moving sight in more senses than one. There are plenty of them; Russell, Dugan and Stewart's "Astronomy" states that it is not at all unusual to find as many as 20 at once on the sun's limb. In 1916 (May 26) one was seen to reach the height of 500,000 miles, ascending at the rate of 20 miles a second. Can you imagine yourself sleeping late on a Sunday morning if you had a spectrohelioscope and could watch such stupendous cosmic events as these? Golf would not pull you away from the eyepiece, nor would motoring. No doubt when the dinner hour came your family would have to feed you forcibly.



Solar prominence seen through spectrohelioscope

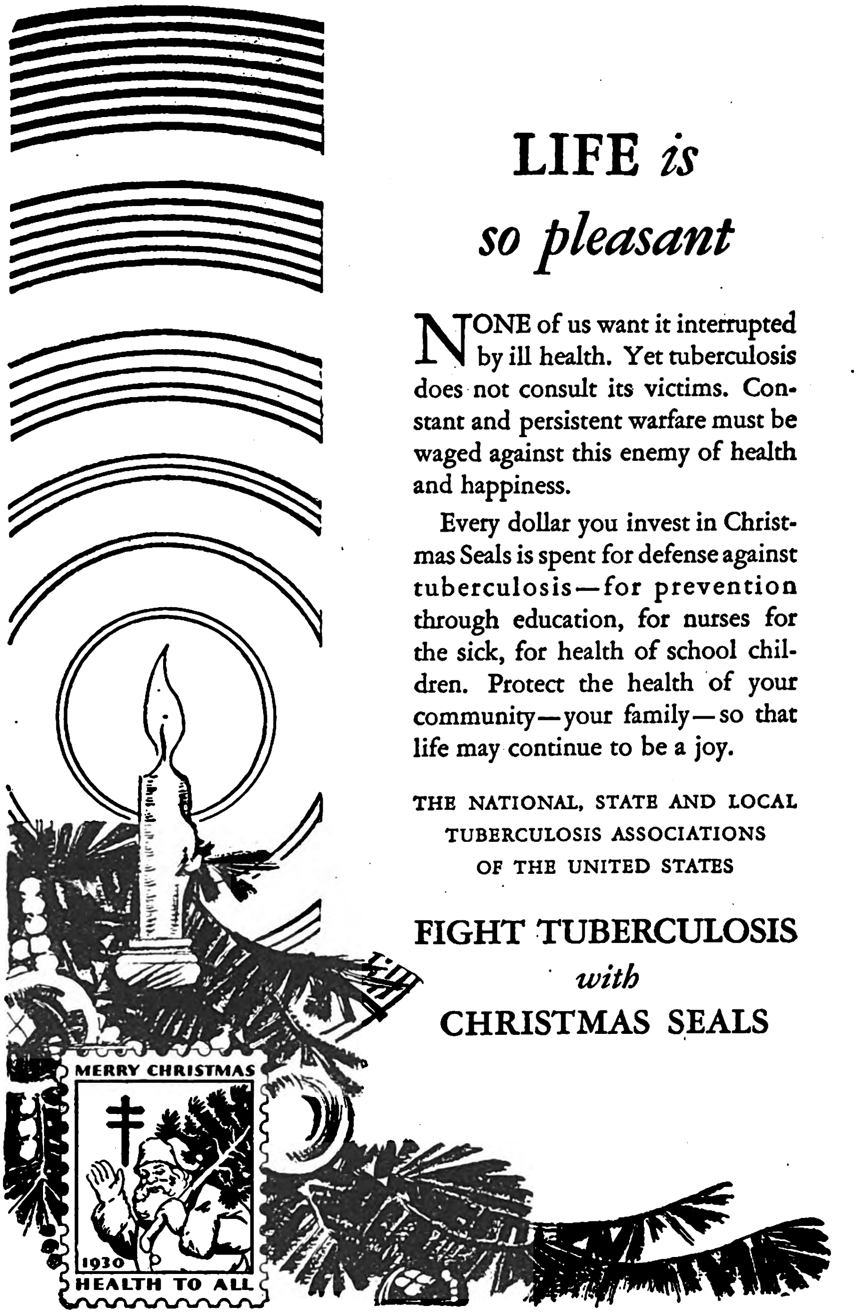
FOR some months we have known that Professor George W. Ritchey had secured the necessary financial backing to begin work on a large telescope of the Ritchey-Chrétien type. He now has made this fact public. He proposes to build a reflecting telescope, of aperture not yet announced, and Miami, Florida, has been selected tentatively as the site. Robert Henkel, Gar Wood, the speed boat builder (who long has been an enthusiastic amateur astronomer), and other Detroit people are his backers. G. H. Lutz ("A. T. M.," pages 243-244) will assist him.

The Ritchey-Chrétien telescope was described by Professor Ritchey in a long series of articles in the *Journal of the Royal Astronomical Society of Canada,* beginning with the May-June, 1928 number. It has a short focal ratio and resembles a Cassegrainian except that, instead of a parabola and hyperbola, a combination of new curves is used. This does away with the distortion of stars not in the center of the field, from which all existing reflecting telescopes now suffer. He also plans to use curved photographic plates accurately ground and polished to a sphere of long radius, since the image projected by the mirror or mirrors of a reflector is not flat but is curved or "dished." He has developed several other extreme refinements, all of which if successfully compounded in one instrument should bring about a striking advance in the technique of telescope making and use. [These mysterious curves have been described—mathematically—in the *Revue d'Optique* (Jan. and Feb. 1922). How to put them on glass never has been described. Don't ask us; we don't know. We asked Professor Ritchey once and his reply was that it is "simple," but he did not describe the method.]

CHICAGO now has an organized group of amateur astronomers and telescope makers, so W. L. Dennis, secretary of the Pickwick Society, 4653 Addison Street, Chicago, has advised us. The Pickwick Society is an established amateur scientific organization but its telescope making activities are new. Its membership includes the professional telescope maker John F. Mellish and Professor Philip Fox, Director of the Adler Planetarium, who will act as advisors. The Society already has a seven-inch, two eight-inch, and a ten-inch reflector. Its activities will center in the Planetarium where meetings will be held. Mr. Dennis asks us to enlist the support of all amateurs in the Chicago district. We wish more power to the Pickwickian elbows. What city is next?

WE learn that the Corning Glass Works (Corning, New York) now has available some standard Pyrex sight glasses which happen to be quite suitable for telescope mirrors. There are several sizes: 6 by ½ inch; 7¼ by ¾; and 9 by ¾. The prices are low. These disks seem pretty thin but should "get by" in nearly every case, as the 8 to 1 ratio usually specified allows a large factor of safety. They often contain bubbles but that can't be helped and these do little or no real harm.

TO complete this month's batch of odd items, here is one furnished by J. V. McAdam, Hastings-on-Hudson, New York. To avoid bubbles in a pitch lap, pour melted pitch on cold tool to half desired thickness and on face of cold mirror (first wet with rouge or soapy water) to equal thickness, and then lay the mirror disk on the other, pitch to pitch. Try it. Mr. McAdam also has modified the Rogers finder (see SCIENTIFIC AMERICAN instruction book "Amateur Telescope Making," page 232) by inserting a monocular in the side of the tube, pointed at a second prism mounted within the tube and in line with the main prism where it intercepts no extra light. An ingenious wrinkle. Although it requires a larger prism, it reduces the number of outside gadgets on the telescope and renders the instrument less vulnerable.



LIFE *is so pleasant*

NONE of us want it interrupted by ill health. Yet tuberculosis does not consult its victims. Constant and persistent warfare must be waged against this enemy of health and happiness.

Every dollar you invest in Christmas Seals is spent for defense against tuberculosis—for prevention through education, for nurses for the sick, for health of school children. Protect the health of your community—your family—so that life may continue to be a joy.

Statler

MEANS MORE THAN just "Hotel"

There's such genuine thoughtfulness for your comfort—and so many conveniences in all our houses—that each stay in a Statler is an extremely agreeable experience. There are attentive employees, *trained*, courteous and helpful . . . a wide variety of restaurants . . . colorful rooms, furnished in the modern mode—every one with private bathroom—circulating ice water — a luxurious bed — bed-head reading lamp—and full-length mirror.

Then *every* Statler room assures you of comforts you don't usually associate with hotels: radio reception, a newspaper under your door every morning. These conveniences, backed by Statler Service and the Statler policy of your satisfaction guaranteed, all combine to make "Statler mean more than just 'hotel'."

Fixed, unchanging rates are posted in every Statler room.

THE SCIENTIFIC AMERICAN DIGEST

(*Continued from page* 479)

Ear-phones are made of two compositions: (1) A compound with phenol, similar to Bakelite; (2) A laconite compound which is a mixture of pure shellac, rosin, gum, mica filler, marble dust, and carbon black. Cases of inflammation of the skin have developed from both types of ear-phones.—*M. F.*

◆

SYNTHETIC PRODUCT FOR FIRE-PROOFING WOOD

AMONG the many new developments in chemistry disclosed at the recent meeting of the American Chemical Society was the announcement of a new series of compounds known as chlorinated diphenyls. These substances are derivatives of a new synthetic chemical diphenyl, described recently in these columns. Diphenyl is a milk-colored substance made by uniting two molecules of benzene and is used commercially as a substitute for steam for carrying heat in gasoline refining. By adding chlorine in various amounts to diphenyl, a series of derivatives is obtained, ranging in variety from a substance resembling water to light oils, thick syrupy substances, and a light, amber-colored solid.

In a paper describing this substance, C. H. Penning lists various commercial applications for the new compound, such as protective coatings, water-proofing, flame-proofing, molding, electric insulation, adhesives, printing inks, artificial leather, leather finishing, textile finishing, sealing waxes, and chewing gum.

"One of the first uses considered when the non-inflammability of the resinous form of chlorinated diphenyl was discovered was as a fireproofing agent for wood," Mr. Penning states. It was found that a practically fireproof product could be obtained, but at a cost considerably greater than when the common mineral salts such as ammonium phosphate, are used. The treated wood, however, instead of being brittle and lifeless, as is the case with the mineral salt processes, gains in strength, and is indeed a superior product.

The thick, oily varieties of chlorinated diphenyl promise to be valuable for their high dielectric constant and resistivity, and their low power factor. These insulating properties make them of great interest to manufacturers of electrical equipment.—*A. E. B.*

◆

CIGARETTE SMOKERS COMPETE WITH GAS

THE people of the United States smoked 127,400,000,000 cigarettes in 1929. If each smoker produced 3½ cubic feet of smoke from each cigarette, the aggregate smoke would just about equal the volume of manufactured gas used in the United States in the year.

◆

BRITISH RIDE ON RUBBER BRICKS

RUBBER bricks have been used in slap-stick movie comedies for years, but in some parts of Great Britain the streets are now paved with them. In a report to the Sixth International Road Congress, held in Washington recently, a British delegation told of the success that rubber paving has had in London, Newcastle, Edinburgh, and Glasgow.

The first experiments to substitute rubber for brick and asphalt were made in 1913, it was stated. A rubber pavement in Glasgow, consisting of blocks of rubber 9 by 4½ by 1½ inches, was laid on a concrete base in 1923.

"Traffic in Glasgow is of the heaviest

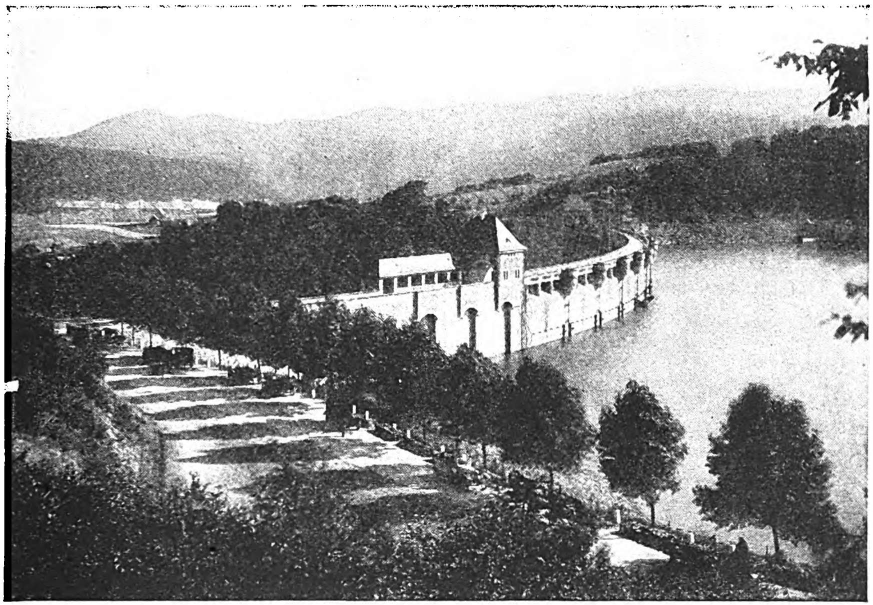
Where "the mountain comes to Mahomet." This bell-type furnace is a recently developed time-saver for heat treating metal in great quantities. The metal to be treated is arranged on top of a base, of which a number are supplied, and a crane covers it with the inverted box-like lid which contains the electric furnace. A number of these furnaces may be operated at one time



Courtesy German Tourist Information Office

Europe's largest power dam forming the Eder Valley reservoir, near the famous health resort, Bad Wildungen. The beautiful lake formed by the impounded water is nearly 17 miles long, 5/8 of a mile wide at its widest point, and has an extreme depth of 137 feet. The sites of three villages were covered. The dam is nearly 150 feet high, 900 feet long at the bottom, and 1300 feet at the top. It has the fourfold purpose of maintaining water in the Weser for shipping, feeding the Mitteland Canal, preventing floods, and furnishing water for power

and most trying class," the report stated. "The cap of one block came away from its tread in 1925. This is the only defect reported. The paving is in good condition and shows no apparent wear after six years' use."

An installation in London was in New Bridge Street, which bears some of the city's heaviest traffic, with 17,623 vehicles, or 51,100 tons between 8 A.M. and 8 P.M., in addition to considerable night traffic. This was laid in 1926.

"After two years of wear, 416 blocks, or say 4 percent, were renewed, and now at the end of the third year approximately another 10 percent have to be renewed," the report stated. "The defects are in the nature of blisters and the subsequent peeling off of thin layers of the cap where blisters appeared. The layers stripped off in no case extend the full surface of a block and are about one fifth of an inch thick; the defects cause no inconvenience to traffic, but they collect dirt and are a blemish."

The paving costs about 22 dollars a square yard, laid without foundation, it was stated.—*Science Service.*

FISH-BONE IN THE LIVER

ORDINARILY a fish-bone seldom shows a shadow when the X ray is used to discover its presence in the human body. Occasionally, however, such a bone may be of such size and density as to be easily visible. Such was the case in a woman, 36 years of age, who had all of the symptoms of gall-bladder disease and who went to a hospital for that complaint. When an operation was performed on the gall-bladder, an abscess was found in the side of the liver and a large, thick fish-bone almost an inch long was removed with the matter from the abscess. Apparently when the woman swallowed the fish-bone it stuck in the wall of the small intestine, which then became adherent to the lower surface of the liver. The fish-bone passed through the wall of the intestines and on through the liver because some of the liver became adherent to the wall of the abdomen.

A careful study of the X ray plates made beforehand revealed the presence of the fish-bone as marked on the plate, although it had been overlooked previous to the operation.—*M. F.*

DISCOVER QUEER PROPERTY OF LIVE WIRES

DOES the passage of electricity through a copper wire cause a change in the properties of the metal? G. C. Oland and C. E. White proved to a recent meeting of the American Chemical Society that it does. The discovery was made by submerging a "live" wire and a "dead" one in an acid solution and measuring the amount of metal dissolved from each in a given time. It was found that less copper dissolved from the wire carrying current, either alternating or direct. Strangely enough, however, when lead, nickel, aluminum, or iron wire was used, the metal was attacked more readily while it was carrying a current.

Encouraged by this discovery, the chemists are continuing their experiments to discover the exact physical and chemical changes caused in a metal by the passage of electricity. Perhaps their work may eventually enable chemists to answer the question that has "stumped" physicists and electricians—what is electricity?—*A. E. B.*

BEETLES CHEW HOLES IN LEAD PIPES

THE supposition that metals can be injured by boring and gnawing insects has been confirmed recently by O. Bauer and O. Vollenbruck as a result of systematic experiments in the Kaiser Wilhelm Institut für Metallforschung and in the National

Wings of Opportunity

ARE you standing on the sidelines, wishing you were in Aviation . . . envying those who are already making Aviation history while holding down good jobs with fine futures? If so, remember this:—*Wishing won't get you into Aviation—but practical training will!* Lt. Hinton's free book, "Wings of Opportunity," tells you a quick, sure, inexpensive way to get the necessary practical training—in your spare time, at home.

Hinton's personalized training and his free Employment Service are putting serious-minded, red-blooded men like you in good flying and ground jobs right along, at salaries of from $40 to $80 a week with Martin Co., Curtiss-Wright, Curtis Flying Service, Alexander Aircraft, T. A. T., Fokker and scores of other *leaders.* In one day alone, we had calls for more than forty men!

Write for this FREE Book Now

If you're 16 or over—and serious about wanting to get into Aviation, get a free copy of Lt. Hinton's book. It tells how he can give you the vital facts, the necessary knowledge of plane-construction, engine-design, rigging, repairing, servicing, airport management, navigating, theory of flight, etc. If you want to learn to fly, his course can save you many times its cost in cash. It's interesting and easy to understand from the start and packed with facts that mean success for you—no matter what branch of Aviation you choose to enter. Mail the coupon today—right NOW.

Gets Job as Aeronautical Draftsman

"After completing your course I was engaged as Aeronautical Draftsman by a leading concern. I thoroughly recommend your training. It is complete in every detail."—Ira W. Bergen, Brooklyn, N.Y.

$50 a Week After Completing Course

Another Hinton Graduate, John J. Morton of Bayport, L.I., writes that he secured a position with the Sickler Flying Service at $50 a week, immediately after we recommended him for it.

Now Chief Instructor at Institution of Aeronautics, N.Y.

Robt. N. Dobbins, a Hinton Graduate, writes: "I cannot thank you enough for the assistance you gave me in getting my present position. Last week they promoted me to Chief Instructor at a salary increase of $15 a week."

CHRISTMAS GIFTS AND CARDS
Christmas Reminder
1930

Make a Christmas Gift to all Humanity

This little
reminder booklet,
for listing Christmas cards
and gifts
you wish to send,
will help you
in your Christmas shopping.
It costs a dollar—
and this dollar goes
into a fight
for the control of cancer.
The fight against cancer
has been waged
for four years by the
New York Cancer Committee,
and has been
the means of saving
many valuable lives
to the community.
Your contribution
will be a Christmas gift
to all humanity.

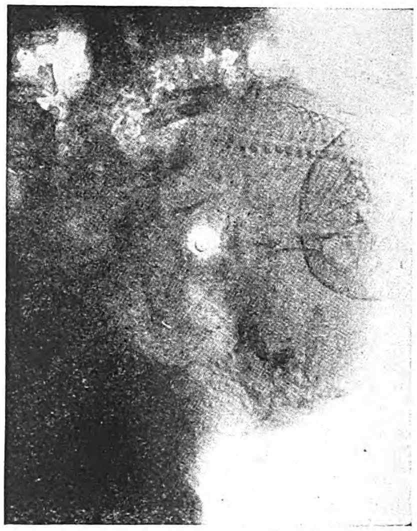
NEW YORK CITY CANCER COMMITTEE
OF THE AMERICAN SOCIETY
FOR THE CONTROL OF CANCER
34 East 75th Street, New York RHInelander 0435

Bureau for the Testing of Materials, says *Industrial and Engineering Chemistry.*

The animals that possess this peculiar metallic appetite are certain varieties of beetles and they are especially fond, it seems, of lead. Cases are on record where the insects have ruined lead, water, and gas pipes, tanks and cisterns, telephone cables, and lead stereotype plates. No attacks of the beetles on aluminum, zinc, or brass could be verified.—*A. E. B.*

DIAGNOSIS OF TRIPLETS BY THE X RAY

OBVIOUSLY it is of importance to diagnose the presence of twins and triplets before their birth. There are many ways in which the physician may do this. He can locate two heart beats, he can feel with his hands the outline of two heads and two spines, and there are various other ways by which he can gain information with his ordinary senses. When, however, there are three children present the situation becomes much more difficult. Hence it is that the X ray was warmly welcomed by the obstetrician as an aid in his work. Dr. Leo A. Rowden in the *British Journal of Radiology* presents the X-ray picture of a case in which, because of the large size of the abdomen, the presence of twins was suspected. Pictures taken from the front and from the side indicated the presence of triplets that lay in the abdomen in various positions. The three children were born on September 19; two of them arrived in the normal order and one reversed.—*M. F.*



Triplets revealed by the X ray

SMOKE-POT WIND INDICATORS

UNITED AIRPORTS of California is marketing with some success a smoke-pot wind indicator. The smoke pot uses cheap fuel oil, holds 25 gallons at a filling, and will produce smoke continuously for 12 to 15 hours without refilling. Any shade of smoke from black to white can be readily produced in accordance with local conditions. The smoke column is heavy and tends to roll along the ground for several hundred feet. Its nominal cost is worth considering. But the mere size of the column as compared with a wind cone or vane is more of an advantage. Also the column bends and veers with every gust and so gives the pilot a precise and instantaneous idea of what the air is doing on the ground.—*A. K.*

FOSSIL WOOD RESEMBLES MODERN PINE

A PIECE of petrified wood from Yellowstone National Park, so perfectly preserved that even the finest microscopic details are practically as clear under the high-power lens as those of modern wood, is described and illustrated in the *American Journal of Botany* by Prof. H. S. Conard of Grinnell College.

It was found in a region where the only previously described petrified woods were those of redwood trees, but its structure is more closely akin to that of one of the species of pine found in the park. Before it could be studied and photographed under the microscope, bits of it had to be ground down thinner than tissue paper, so that light would shine through.—*Science Service.*

OUTBOARD MOTOR AERATES FROZEN LAKES

OUTBOARD motors, advertised by manufacturers as a most valuable aid in transporting fishermen to the scene of their nimrod activities, take a new rôle in the winter—this time assisting the fish. This information was recently received by the Johnson Motor Company, Waukegan, Illinois, from a South Dakota dealer.

In one instance the state game warden called on W. T. Williams, Watertown, South Dakota, owner of an outboard motor, to save the fish suffocating under the ice in a small lake near Goodwin.

Mr. Williams built a stone-boat frame to set his motor in, and hung it at a tilt in a hole through the ice about three feet by six feet. In this position the propeller of the motor threw a heavy flow of water out and over the top of the ice. About 300 feet from the motor, he cut five holes about three feet in diameter, as shown in the accompanying sketch.

The motor was started and ran six days and nights constantly. About every six or eight hours the motor had to be moved back several feet because of the washing away of the ice.

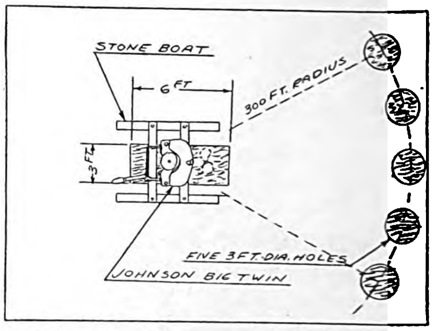


Diagram of how an outboard motor was used to aerate a frozen lake

During the six days a crew of fishermen seined 760 dollars' worth of scavenger fish from the lake, leaving an aerated lake with enough fresh water to save the game fish.

Several times after long continued cold spells, the state game and fish commission have aerated various lakes in this manner.

CURRENT BULLETIN BRIEFS

SHORT REVIEWS OF BULLETINS AND PAPERS ON SCIENTIFIC AND ALLIED SUBJECTS, AND WHERE TO GET THEM

STAPLE VITREOUS CHINA PLUMBING FIXTURES (Commercial Standards CS 20-30, Bureau of Standards) gives valuable diagrams (with sizes) of various plumbing fixtures. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

COPPER ELECTROTYPING (Circular of the Bureau of Standards, No. 387) gives an exceedingly valuable resumé of the process and will prove valuable to all who are in any way interested in plating. *Superintendent of Documents, Washington, D. C.—10 cents (coin).*

ANNUAL STATISTICAL REPORT OF THE AMERICAN IRON AND STEEL INSTITUTE FOR 1929 gives 129 pages of carefully prepared statistics, the tables being very authoritative. *American Iron and Steel Institute, 75 West Street, New York City.—$5.00.*

THE DIFFERENTIAL ANALYSIS OF STARCHES (Publication 275—Field Museum of Natural History, Botanical Series Vol. IX, No. 1) by James B. McNair. *Field Museum of Natural History, Chicago, Ill.—50 cents, plus postage.*

GROWING BLACK LOCUST TREES (Farmer's Bulletin, No. 1628, U. S. Department of Agriculture) by Wilbur R. Mattoon, tells how to grow trees for which there is a demand, particularly for fence posts, stakes, insulator pins, and tree nails. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

ENGLISH SPARROW CONTROL (Leaflet No. 61, U. S. Department of Agriculture) by E. R. Kalmbach gives economical and effective methods for local control of this pest. While the nestlings eat insects, this is only for ten or twelve days, whereupon they become confirmed vegetarians. *Superintendent of Documents, Washington, D. C.—5 cents (coin).*

DE FLOREZ MANUAL CONTROL SYSTEM (Bulletin No. 7520). With this system the operator can almost "feel" the movement of the distant control. The pamphlet tells how. *The Brown Instrument Co., Philadelphia, Pa.—Gratis.*

FIFTY COMMON PLANT GALLS OF THE CHICAGO AREA (Botany Leaflet 16, Field Museum of Natural History) by Carl F. Gronemann, while perhaps of local interest, gives excellent illustrations which are botanically correct. *Field Museum of Natural History, Chicago, Ill.—25 cents.*

PASSING THROUGH GERMANY is the title of a delightful little travel book of 225 pages, beautifully illustrated. It is not a guide book in the ordinary sense, but takes care of such subjects as the fine arts, vacation study, German politics, et cetera. This beautiful little book is sent for the cost of the postage which can be remitted by two international reply coupons which will cost ten cents.—*Terramare Office, Wilhelm Strasse 23, Berlin, S. W. 48, Germany.*

FUNDAMENTALS OF PATTERN DRAFTING FOR SHEET METAL SHOPS is an excellent little treatise on the subject and is well illustrated. *Publicity Department, The American Rolling Mill Co., Middletown, Ohio.—Gratis.*

HOW WE MAY GET VITAMIN A; B AND G; C; D (Extension Circulars, Extension Service of College of Agriculture, University of Wisconsin) are four little pamphlets giving radio talks by Mrs. May Raynolds of the Home Economics Department, University of Wisconsin. *College of Agriculture, University of Wisconsin, Madison, Wis.—5 cents each.*

WAYS AND MEANS TO TRAFFIC SAFETY gives the recommendations of National Conference on street and highway safety as summarized and approved by the Third National Conference, May 27-29, 1930. *National Conference on Street and Highway Safety, 1615 H. St., N. W. Washington, D. C.—Gratis.*

AERONAUTIC PUBLICATIONS (Aeronautics Bulletin No. 6, Aeronautics Branch, U. S. Department of Commerce) is a valuable pamphlet citing books and periodicals pertaining to aeronautics. It also gives a complete list of the Aeronautics Bulletins, 25 in number, which are sent free (with one exception) to interested parties. *Aeronautics Branch, U. S. Department of Commerce, Washington, D. C.—Gratis.*

THE AERONAUTICS BRANCH, DEPARTMENT OF COMMERCE (Institute for Government Research, Service Monographs of the United States Government No. 61) by Laurence F. Schmeckebier, deals with the history, activities, and organization of this important branch of the government service. It contains much information unobtainable elsewhere. *The Brookings Institution, Washington, D. C.—$1.50.*

OBSERVATIONS ON THE POSSIBILITY OF METHYL CHLORIDE POISONING BY INGESTION WITH FOOD AND WATER, by W. P. Yant, H. W. Shoaf, and J. Chornyak. While there is no definite evidence that food poisoning has occurred or that this type of hazard exists with the refrigerants in current use, nevertheless, the possibility is a matter of concern to manufacturers of refrigerating devices and products, to health officials, and to the public. This detailed study will prove of service to all such persons. *The Roessler & Hasslacher Chemical Co., Niagara Falls, N. Y.—Gratis.*

1931 LOWEST WHOLESALE PRICES! FREE RADIO CATALOG
Everyone interested in RADIO should have this Catalog. Solid with "Specials" from cover to cover. Teeming with values ... every item a feature. All latest sets and equipment. Lathe Builders for 24 Years — Over 50,000 in Use

THE SALVATION ARMY

in the United States celebrates this year its Jubilee. Fifty years ago one man and seven lassies landed at the Battery, New York City, the pioneer band of a new evangel. Since that day the organization has steadily advanced to the high place it now occupies in the esteem of the nation. Religion in action is the basis of all its endeavor. No barriers of race, creed or color are recognized.

Every year the Army marks the festive season by giving Christmas dinners to the deserving poor and toys to underprivileged children, in addition to the year-round care of all who seek its aid, temporal or spiritual.

You are invited to share in this beneficent work by easing the financial burden.

Will YOU Help?

OUR POINT OF VIEW

(*Continued from page* 429)

from laying off men or reducing wages. Nor is there much substance in the statement that this reduction does not add to the unemployed because men are not discharged until the end of their enlistment. There is a continuous outflow of men from the Navy and unless there is a corresponding intake, the average in the Navy quickly drops. Briefly stated, the Navy Department will draw upon the labor market for just 4800 less men after this reduction, and the ranks of the unemployed are swelled by exactly the same number.

We sympathize with the President's effort to reduce government expenditures in order to avoid raising the income tax; we are aware of the enormous strains put on the Treasury by the operations of the Farm Board, the building of Hoover Dam, the accelerated public-building and road program, and last, *but not least,* the increased cost of prohibition enforcement; we know that powerful interests would oppose any cuts in these expenditures, while there will be few in public place to protest a naval slash. Some of the President's advisers may think it is good politics to save at the expense of the Navy, but we know they are wrong and are confident that the great inert mass of unorganized Americans, patient though they be, will find a way to show their resentment of a continuous surrender of national interest to placate organized groups held together by fanatical, short-sighted, or selfish motives.

Continued Unrest In South America BRAZIL, the largest and most important of the South American states, is in the throes of a revolution that appears at this writing to be succeeding. Already more blood has been spilled in Brazil than in the "palace revolutions" of Argentina and Peru. Probably the fundamental cause of this revolt is the economic depression occasioned primarily by the low price of coffee, Brazil's great export commodity; the alleged cause is that President Luis was elected by gross frauds perpetrated under the protection of the army; unquestionably, the rather easy successes of the revolutionists in Peru and Argentina, followed by their rapid recognition as *de facto* governments by this country, encouraged the present outbreak in Brazil.

This present unstable condition throughout Central and South America, we feel sure, is being carefully considered by the State Department. In general the European powers follow our action in extending recognition to the revolutionary governments, so that our responsibility, though undefined, is immense. Usually our government views with disfavor any violent usurpation of authority, and in a treaty with the states of Central America agreed to withhold recognition from a government based on force. This agreement does not extend to states of South America, and obviously different conditions will require different methods of treatment.

Our investments in Central and South America are colossal. One expert estimates that we have a total investment of 6.000,000,000 dollars in these countries and an annual export trade to them of 1,000,000,000 dollars. Brazil alone takes 100,000,000 dollars of our exports annually; Argentina, 180,000,000 dollars; Cuba, 125,000,000 dollars; and Mexico, 115,000,000 dollars. Thus we have a large economic interest in our southern neighbors.

In addition to the revolution in Brazil, President Machado of Cuba has been authorized by the Cuban congress to suspend the constitutional guarantees in that country on account of threatened outbreaks in Havana. There are also fresh indications of unrest in Mexico. Former President Portes Gil, resigned as head of the National Revolutionary Party, and General Plutarco Calles, reputed strong man of Mexico, issued a warning that the Government must purge itself of disloyal factions. Presumably in response to this threat, Louis Leon, Secretary of Labor and Commerce, resigned and other cabinet retirements are rumored.

The Monroe Doctrine effectively prevents European intervention in South American affairs. It therefore carries a moral obligation on our part to exercise the stabilizing influence which would otherwise be exerted by the Great Powers of Europe. The extent and nature of our intervention in the affairs of our proud Spanish-American cousins can only be determined after careful consideration of the many factors involved; each situation that arises has to be considered on its own merits since no precise rules can be formulated that will cover the various crises that continually arise.

Americans will understand the delicate dilemmas that almost continually confront the Department of State if they will visualize the Latin-American situation as it actually exists and realize that republican institutions and representative governments are ill-adapted to the genius, habits, and mental outlook of the Central and South Americans of Spanish descent, who constitute the real ruling class in these countries and who are entirely unconvinced that the ballots of ignorant *mestizos* should decide the destinies of their countries. The great bulk of the peon population is content to leave the government in the hands of the small ruling class, and the so-called revolutions, for the most part, are merely struggles between certain cliques or oligarchies for power. The prevailing economic depression causes unrest, and the oligarchies out of power have simply taken advantage of it to seize the government.

Our interest lies in the orderly self-development of these countries. We can not force this development which must be a slow evolution; we can carefully avoid hindering this development by officious meddling with their domestic concerns, and we can by friendly counsel decrease the number of, and lessen the savage severity that sometimes marks, these revolutionary shifts of authority. And at all times we can protect these states from foreign intervention which would further complicate their already difficult problem.

It is a singularly fortunate fact that Mr. Hoover toured Latin-America prior to his inauguration. This visit, intended mainly as a gesture of our friendship for its people, has furnished him valuable first-hand information of conditions in this important and temporarily disturbed region. The President's personal knowledge of the situation will assist him to determine practical measures to be undertaken by the United States. And our President should not be hampered in his efforts by uninformed critics or partisan politicians.

The British Imperial Conference THE Imperial Conference composed of delegations from the self-governing dominions and India, opened in London with Premier MacDonald presiding. Many important questions will be considered by the Conference but the most interesting one was disposed of before the Conference met when a member of the British Government formally conceded the right of any British Dominion to secede from the Empire. It had been expected that Premier Hertzog of the Union of South Africa would assert the claim of his dominion to withdraw from the Empire voluntarily, and there were some that professed to believe the British government would contest the claim.

The attitude of the British Government in this matter is just one more instance that the British Empire differs fundamentally from all previous empires, for it is impossible to imagine any other ancient or modern empire permitting a province to pass from its control without a struggle.

The decision of the British Government is probably based on two primary considerations: (1) The inability of the loose-jointed Empire to coerce an unwilling dominion; (2) The unprofitableness of retaining a reluctant member in the Empire. Our successful revolution in 1776 changed the whole attitude of the British people towards their colonies, and the enormous military effort necessary to subdue the Boers in 1899 convinced the British people that it would be poor policy indeed to attempt to keep a dominion in the Empire against its will. The announcement of the government is but an official acknowledgement of an already tacitly accepted principle; none-the-less its formal admission marks an epoch in imperial politics.

In addition to the sentimental ties that bind the dominions to the United Kingdom, there is the very practical consideration that the British Navy and Army are always ready to defend the dominions from external aggression. An Australian or Canadian pays a small tax for the defense of the Empire compared to the tax paid by a resident of the United Kingdom. And we imagine the right to secede will remain in academic abeyance for a long time to come.

The Conference is seriously studying the possibilities of intra-Empire trade, and while the difficulties confronting the Conference are apparently insuperable, it is altogether probable that some measure of trade preference within the Empire will be evolved. It will have to take some shadowy form that will not frighten the Free-traders in the United Kingdom who violently oppose taxes on food, or the Protectionists in the Colonies, who are seeking to build up their factories. Whatever form it takes, any success obtained is almost bound to be at the expense of some of our trade with the United Kingdom and with the dominions. One reason for the British dislike of Briand's proposed United States of Europe was the economic union of continental Europe that would accompany such a development, and the adverse effect it would have on British trade. The struggle for world trade is increasing and is the secret source of many of the so-called policies of the great powers.

A Ray of Hope in China YOUNG Changsu Lin, ruler of Manchuria, took advantage of the exhaustion of the warring factions in Central China, and marched without opposition into Peking. Ostensibly he came to the support of the Nationalist government, the new capital of which is Nanking, which had entirely absorbed its energy in resisting rebellious war lords.

While outwardly the power still is in the hands of the Nationalists, actually it lies with Chang and his army. Manchuria has been enjoying law and order while the rest of China has been devastated by civil war; so far as Chang is able to extend his dominion, he will restore peace to the distracted Chinese. If the Nationalists can accommodate their somewhat visionary plans for a Chinese republic with Chang's personal ambitions, they may obtain the use of his army. This combination would enable them gradually to extend their authority throughout central China. But until there is a much stronger feeling of nationalism and patriotism in China than there is today, all ideas of establishing a unified Chinese republic are chimerical.

Chang's father was too ambitious personally to unite with other Chinese leaders, and it is more than probable that the son will prefer to play a lone hand. If so, his support of the Nationalist government will be of short duration. If, on the contrary, a basis of agreement can be found, a fairly stable government extending from Mukden to Shanghai, including Peking and Tientsin, could be set up. If autonomous governments are achieved by local chiefs in south and west China there would be a lull in the civil wars. In time, if unvexed by foreign interventions, these various Chinese provinces would be drawn into some loose form of confederation; and when roads and railways permit fairly rapid communication between its widely separated provinces, a real unification of China may be expected to begin.

MORE ABOUT PLUTO

(*Continued from page* 447)

keep near one another for almost half a revolution.

At such a time the mutual perturbations must be large, but it will be long enough in all conscience before they can be used to find the masses. Uranus and Pluto also come close to commensurability of periods, for the former completes its revolutions in 84.02 years and three times this is only 2.9 years greater than one revolution of Pluto. The planets therefore return to almost the same relative position after 250 years—during which interval Uranus catches up with Pluto twice.

Figure 3, which is very much like the last one, shows the positions of the planets. At the last conjunction in 1853 the distance of the planets was 30 astronomical units—about the greatest possible. At the next, in 1965, the distance will be only half as great. The perturbations then will be much larger than in the past century and should lead to a fairly good determination of Pluto's mass—*Paris, September 17th.*

Scientific American!

FACTORS IN THE SEX LIFE OF 2200 WOMEN

By Katharine Bement Davis, Ph. D.

This pioneer volume offers concrete factual data on the events in the sex life of normal women, supplying needed information on a topic which has long been the subject for uninformed conjecture.

Under the expert direction of Dr. Davis, two groups of selected women—married and unmarried—replied anonymously to questionnaires designed to elicit information on every phase of woman's sexual life. Full data on the various periods of life, as well as on so-called "abnormal" experiences were received.

This information was first tabulated. Then comparative statistical studies were made on the most important topics. The book offers specific data on many questions like: What factors seem to enter into the "happy" and "unhappy" married life? What are the causes and extent of abnormal practices? What is the importance of sexual education, etc.?

The clear and simple treatment makes the book invaluable to social workers, physicians, parents, educators; first in developing a saner attitude toward the whole subject; second as a tested method in throwing light on sexual maladjustments as affecting personal relations.

The Scientific American says: "Almost to a certainty this book will upset a number of fondly cherished beliefs. It is a thoroughly scientific record of scientific work in sociology, performed by a noted scientific authority. The discoveries recorded were based on actual data secretly obtained." For free examination, use the coupon now. Price $3.50.

AVIATION IN 1930

(*Continued from page* 465)

casualties took place in wrecks, but considering all of them the rate is approximately one death per 300,000,000 passenger miles. For the year 1929 there was a death rate among airway passengers of one death in 9000 flights. If an average trip of 300 miles is assumed, this develops into a rate of one death for each 2,700,000 passenger miles. The discrepancy in favor of the railroad is formidable, still not necessarily too formidable.

What is encouraging is that aviation, whether governmental, engineering, scientific, or operational, is fully aware of the importance of increasing safety. The methods of increasing safety are so numerous that they can only be presented in the briefest fashion. But perhaps the following will give a picture of the energy and comprehensiveness of to-day's effort towards safety improvement.

The Guggenheim Safe Aircraft Competition produced a plane, the *Tanager,* equipped with the famous Handley Page slot, which was able to come to rest in 100 feet after touching the ground.

The National Advisory Committee for Aeronautics has undertaken the systematic study of "spinning," that much dreaded cause of accidents, and is evolving valuable data which should enable designers to build planes immune from such troubles.

The Aeronautics Branch of the Department of Commerce has inaugurated a system of licensing airlines, and of licensing only those airlines which are satisfactory in personnel, equipment, and ground organization.

The perfection of radio communication between plane and airport, and the use of such communication by important airlines has arrived simultaneously with the provision of a nation-wide weather service.

Instrument manufacturers are bestirring themselves to produce instruments which will give reliable indication to the pilot in fog flying. At the same time the technique of fog flying is better understood, and systematically imparted in the training of reserve pilots. (See page 430, of this issue.)

The Bureau of Standards has perfected its system of radio beacons, and is now experimenting with a system which will enable the pilot to land safely in fog.

The insurance companies are inspecting planes and airlines and granting better rates to companies of more than usual status from the point of view of safety.

The Packard Diesel engine for aircraft, allowing the use of heavy fuel-oil, removes or diminishes the fire hazard.

The licensing of schools, and the licensing of transport pilots and ground mechanics is improving the status of the operating personnel.

Safety will come as a result of all such efforts, and their value is cumulative.

The aviation industry is at present undergoing a period of severe depression. Many of the smaller airplane manufacturers are closing down, others are retrenching severely on personnel and cutting down on production; two of the biggest holding companies have issued reports showing enormous losses both absolutely and in percentage of invested capital.

Using a hackneyed phrase, the industry is nevertheless sound. The present difficulties are partially due to the general depression now ruling in the United States, partially to the wave of optimistic enthusiasm which swept over the aviation industry soon after Lindbergh's flight. The manufacturers over-estimated the number of planes the public would buy. The schools over-estimated the number of students likely to enroll. The companies erecting airports over-estimated the growth of student instruction and of private flying, and underestimated the effects of competition in the form of municipal airports. With this enthusiasm there followed a period of over-capitalization, with the public putting up far more money than the industry could profitably employ, so that at the present time the average return on aviation investments is negligibly small.

Yet the industry is growing rapidly all the time. It is only the rate of growth which has been misjudged.

Several favorable factors are already at hand. The Aeronautical Chamber of Commerce reports that the production of new planes is falling slightly behind sales, which indicates that inventories are being slowly liquidated. Severe price reductions which have recently come into effect will hasten this process of liquidation.

Another favorable feature lies in the export of American aircraft. The American industry is exporting an increasing portion of its production. In 1929 nearly 14 percent of its total production value was exported, mainly to Central and South America. At the same time there was a change in the character of the exports. War material and small training planes have been replaced, as far as exports go, by large transport planes of far greater value. As a result of this change, the value of American aircraft exports has more than doubled in the last three years. Nor have exports fallen off substantially during 1930, the worst of all years. For the first six months of 1930 they have totalled 3,256,584 dollars against 3,589,196 dollars in the first six months of 1929.

Again, American air transport is growing rapidly and steadily. The merger of New York, Rio, Buenos Ayres Airlines with Pan-American has resulted in the formation of the largest and most powerful air transport system in the world. In a very few years it will connect every important port in Central and South America with the United States. Pan-American is not only carrying vast quantities of mail, but with the use of large and reliable flying boats or amphibions it is also transporting a larger and larger number of passengers. In the United States progress in air transport is equally rapid. The Aeronautical Chamber of Commerce reports that 133,000 passengers were carried by 29 major transport lines in the first six months of 1929. The poundage of freight and mail was equally impressive, showing 137,398 pounds, with 82,165 pounds carried in the second quarter. The Watres bill which will allow the Postmaster General to place contracts for mail on a space basis and will permit the carrying of mail on passenger airplanes will serve to stimulate the growth of air transport still further.

There is not the slightest doubt that aviation will rapidly work out of the slump and in a few years assume gigantic proportions.

BOOKS SELECTED BY THE EDITORS

ARTIFICIAL SUNLIGHT—*By M. Luckiesh, D.Sc., Dir. Lighting Research Lab., G. E. Co.*

IF Dr. Luckiesh, out of his extensive practical experience with illumination and laboratory testing, set out to write a book suitable for the professional man and intelligent layman alike, he has succeeded in his purpose. Not only the specialist and the general practitioner in medicine, but the average reader would equally well be able to suck the juice from this scientific, technical but not abstruse, though not light-weight, work. Thereafter he would have an advantage over the rest of us who read or hear various claims about the ultra-violet and the infra-red for health benefit but cannot judge of their accuracy because we do not know the "whys" of the subject. But this book is a veritable "why" mine. It covers both solar and artificial radiation and their physiological effects, their measurement, measurement of the ultra-violet, glasses for transmitting it, various artificial sources, and the infra-red.—$3.90 postpaid—*A. G. I.*

STUDIES IN THE LITERATURE OF NATURAL SCIENCE—
By Julian M. Drachman

THE author traces the effect of scientific writing—largely popular and semi-popular, such as that of Darwin, Tyndall, Proctor, Spencer, Eddington—on public opinion and changed public outlook, and therefore on our present age, the Age of Science. Readers who have made an intelligent effort to grasp the real significance of our age in world history will find this book a valuable addition to their library.—$4.20 postpaid—*A. G. I.*

KNOWING that often there is a name or names on the Christmas shopping list for which it is difficult to find something appropriate, we have this month in these pages given you a number of books suitable for Christmas gifts, both for the young and for the adult. We suggest that a well chosen book makes as gratifying a present as can be made.

In the past we have found that many of our readers like to have a cheery Christmas card slipped into the book they give, the donor's name being neatly typed thereon. Our Book Department will be glad to do this for you if you so desire. The whole makes a most acceptable and appropriate remembrance and if you act at once there is ample time to post even to a distance.—*Book Editor*

COMETS—*By C. P. Olivier, Dir. Astronomy, Univ. of Pa.*

THE well-known author of the standard work, "Meteors," foremost American authority on this branch of astronomy, now has written one on the very closely allied subject of comets. It is a popular book of 239 pages and discusses comets from every angle likely to interest all except the incurable mathematician; it is non-mathematical. There has been no such book and this one was needed.—$3.65 postpaid—*A. G. I.*

CLIMATE—*By C. E. P. Brooks, F. R. A. I.*

THIS small work contains descriptions of climates in different parts of the earth. Students of climatology might not find it dull, most others would because of its formal language and the fact that it is for the most part a compilation of statistical data.—$3.20 postpaid—*A. G. I.*

SOIL—*By Archer Butler Hulbert*

"WHAT of the soils?" "What do they produce?" "Could we master the land by the tricks of the trade that we learned at home?"—such questions as these, put to such exploring pioneers as Daniel Boone on his return from the Western Reserve and to Lewis and Clarke on their return from the Pacific, constitute the keynote of this interesting study. It is the story of the influence of the soil on pioneer settlement of this country, with particular reference to migration and the scientific study of local history as it was made by various national groups. "Soil" should be read for its interest and then placed upon one's bookshelf as a valuable reference book.—$2.65 postpaid—*F. D. McH.*

SCIENCE AND THE SCIENTIFIC MIND—*By L. E. Saidla and W. E. Gibbs*

TWENTY-FOUR essays by some of the most noted figures in the world of science, such as Millikan, Soddy, Pupin, Haldane, Slosson, et cetera. An interpretation of those methods of thought which have determined the character of the present age. Five hundred and two pages include valuable appendices of suggested reading and a quite complete list of biographical notes, the whole forming a scholarly and well outlined exposition for mature cultural consideration.—$3.20 postpaid.

THE BOOK OF GLIDERS—
By E. W. Teale

A COMPLETE manual telling all about their construction and operation as well as the history of gliding, with illustrations of famous gliders. The preface is by W. H. Bowlus, American Glider Champion. Clear diagrams elucidate the text and complete plans down to the smallest part are given to build a glider which was especially designed for the book, to take in all the best features of those that had previously been built. Records, licenses, organization of clubs, et cetera, naturally are also included in the volume.—$2.65 postpaid.

THE WONDERFUL STORY OF INDUSTRY—
By E. F. Baker

WELL told stories of how many of the common commodities of our daily life are made; newspapers, matches, bread, ice, glass, hats, shoes, coffee, tea, and so forth. Just such details as will satisfy the inquiring youthful mind. Twenty-five subjects in all and all explained to bring out the romance of manufacture and the dignity of labor. A fine book for the young acquisitive mind.—$2.65 postpaid.

EARLY AMERICAN FURNITURE MAKERS—
By T. H. Ormsbee

QUITE an unusual viewpoint is taken in this survey of the great manufacturers, by stressing the economic, social, and political conditions under which the personality and art of the individual were developed. One hundred and twenty-two illustrations ably depict the craftsmanship of the producer and many chatty narratives give glimpses of the times and customs. A handsome format with end leaves giving an interesting chart of the periods in which the furniture was produced. A fine library volume, with good human interest values.—$3.65 postpaid.

FROM RECENT PUBLICATIONS

FAMOUS EVENTS IN AMERICAN HISTORY—
By Inez N. McFee

JUST as its title proclaims, 20 major events in our history have been selected by this very successful writer, to represent various phases in our national life. With the art of the natural narrator are spread before us the importance and the picturesqueness of heroic accomplishments which were vital steps in our progress, from Columbus to Byrd. The sort of reading grownups as well as youngsters can enjoy. A suitable gift book.—$2.20 postpaid.

HEAR WITH YOUR EYES—*By M. E. Good*

RECENTLY a caller confessed to this reviewer that she had made quite a study of lip reading because she was somewhat deaf and was sensitive about people knowing it. This unique little book outlines by photographs and description a natural method of reading word-forms on the face. The system is simplicity itself and the entire scheme is condensed into 40 pages of text. Sir Richard Paget states that primitive man originated a system of this kind and our modern alphabet developed therefrom. We commend it highly. —$1.15 postpaid.

FOUNDATIONS OF BUDDHISM—*By Natalie Rokotoff*

BECAUSE of the serious unrest in India today this little volume of 137 pages with its crisp, delineating style, will be found to outline clearly the foundations of the forces which keen observers say will eventually make for revolution. One can scarce read with intelligence the news of the day without some background such as is here given.—$1.65 postpaid.

STRATEGY IN HANDLING PEOPLE—*By E. T. Webb and J. J. B. Morgan*

A BUSINESS man and a psychologist have culled much biographical material to illustrate psychological principles with incidents from the careers of famous men and to show how they have handled our own familiar problems in dealing with people. So successfully has this been done that one seems to be reading intensely personal biography rather than an application of psychology. A most unusual presentation approved by a long list of notable scholars.—$3.20 postpaid.

TRAITOR! TRAITOR!—*By J. D. Kerkhoff*

FOR the first time in the English language is told the complex story of the tragedy of Alfred Dreyfus' persecution by the French Army, which stirred the world. His life on Devil's Island beggars imagination for its fiendish cruelty. The acknowledgement of his innocence and the restoration to honor and higher rank with the bestowal of the Légion d'Honneur make some of the most dramatic accounts on record and certainly fail in no point as told by the author. This is an authentic, stirringly dramatic chapter of history that will hold you to every line of the text.—$3.65 postpaid.

THE ATLANTIC—*By Stanley Rogers*

HISTORIES have been written about everything else, why not the history of the Atlantic Ocean—to paraphrase the author. So in most engaging style he sets forth the main events which have taken place thereon; a life story of the old Atlantic herself. The text is charmingly embellished with pen and ink sketches by the author and the whole rivals in interest and instructiveness his previous success "Sea Lore."—$2.90 postpaid.

STORIES OF THE YOUTH OF ARTISTS—
By Mary Newlin Roberts

ANY boy or girl not necessarily artistically inclined, should like these stories of youthful aspirations and dreams of other young people who made their dreams come true. Exceedingly well told in a dignified yet simple manner, the format is most attractive and well executed, the whole forming a book that would be a most acceptable Christmas gift.—$2.65 postpaid.

STORIES OF LOVE, COURAGE AND COMPASSION—
By Warwick Deeping

HERE in 821 pages the author has gathered the best of his shorter fiction: three short novels and 48 short stories covering a tremendous variety of subjects. Appreciators of Deeping will find herein probably a more satisfactory insight into the warmth and breadth of his style and his overspreading humanity than it has been possible to obtain in any one of his previous popular stories. A veritable omnibus of enjoyment.—$3.25 postpaid.

CAMPING AND SCOUTING LORE—
By Atwood H. Townsend

PRACTICALLY every phase of the subject has been fully covered in this very complete book of 366 pages for boys and girls of ages 12 to 16. The author, himself the fifth Eagle scout in Brooklyn, presents the subject in a most admirable and interesting manner. Numerous illustrations amplify the text and can be worked from directly. A fine book for home study.—$3.25 postpaid.

TUNDRA—*By The Eddingtons*

A TALE of romance and adventure on Alaskan trails as told by former Deputy Marshal Bert Hansen to the authors. No more entrancing story of the fortitude, indomitable perseverance, and fearlessness of the real Alaskan has been told. Replete with color of character and colorlessness and bleakness of landscape, one's attention is riveted by the word pictures because of their vividness, so the temptation is strong to finish the book at a sitting. Especially strong in its details of dogs and methods of living.—$2.65 postpaid.

HUNTING THE ALASKA BROWN BEAR—
By John W. Eddy

THIRTY brown bears were met and studied in this particular trip although the author had been observing these animals for years. This type of grizzly is the survivor, practically as it existed in the age of mammals, of the contemporary of the mastodon. A fine story of adventure with 44 illustrations.—$3.65 postpaid.

SEPPALA, ALASKAN DOG DRIVER—
By Elizabeth M. Ricker

THE author, herself the holder of records in "mushing" races, has told the mighty interesting story of this colorful

FOR YOUR CONSIDERATION

character who was born in Norway, emigrated to Alaska during the Nome gold rush, and incidentally became a dog driver. The true story of the rushing of serum to Nome is here told for the first time. Incidentally the real dog hero was *not* Balto, as the world was given to suppose, but Togo the lead dog who carried his team 340 miles to Balto's 53. Both dogs were owned by Seppala. A gripping, fascinating story of hardship and adventure.—$3.20 postpaid.

THE REMINISCENCES OF A MARINE—
By Maj. Gen. John A. Lejeune, U. S. M. C.

NO more picturesque character has appeared in the annals of this service than the author, who commanded the famous Second Division which took such a prominent part in the late war. Of Arcadian, French, and British ancestry, with firm religious convictions, he was exceedingly popular and ranked among the ablest in the A. E. F. One will find many surprising facets of character hitherto unknown, as well as much important unwritten history in this tremendously interesting and instructive work of 488 pages. Much of the data of events was checked up from the daily letters to his wife which he wrote even in the midst of battle and during his entire career. Practically the last of the principal American commanders to write his memoirs. Don't fail to read it.—$4.20 postpaid.

HERE COMES PANCHO VILLA—*By Louis Stevens*

SO much of romance has been wound about this "genial killer" that it is most interesting and instructive of Mexican life and law to have the story of the real facts concerning this amazing character. Only now since some years have gone by, has the terror of his vengeance passed to the extent that those who know the facts have been willing to tell them. This man for years defied Mexican and United States authority—the best troops of each nation could not capture him. Indeed some believe he is still alive. We who have wondered how he committed his atrocities and got away, will find mighty interesting reading in these pages.—$2.65 postpaid.

ALARIC THE GOTH—*By Marcel Brion*

FROM innumerable ancient sources the story of the man who sacked Rome has at last been fabricated and we find a character quite different from that presented in most of our histories. Fierce and dominant he was but he sturdily defended the crumbling Roman Empire until his disgust at the feeble, vascillating Caesar and the refusal of military rank commensurate with what he considered his services, roused again the barbarian in him. The sack of Rome followed. Informative, historical and entertaining.—$3.65 postpaid.

BABER: FIRST OF THE MOGULS—*By Fernand Grenard*

BORN of the direct line of Tamerlane, raised in a microscopic frontier province whose passes lead to China, by a most astounding sequence of events Baber became the first of the Moguls—creator of an immense empire in India. Infinitely less known than his ancestor, he has taken the prize away in point of grandeur and permanence of accomplishment. His generalship, his political genius, his genius for organization, the worth of the man himself makes one of the most interesting biographies one could conceive—in fact it is practically an autobiography, for Baber himself set down the circumstantial history.—$3.65 postpaid.

REACTIONS AND SYMBOLS OF THE CARBON COMPOUNDS—*By T. Clinton Taylor, Asso. Prof. Chem., Columbia*

A TEXT which develops the study of organic chemistry on the basis of experimental experience by emphasizing the reaction and explaining fully the steps taken to formulate the symbol. Throughout frequent references are made to the literature and the sources of information. 39 chapters, 704 pages, including a very complete index. A thorough and conclusive work.—$4.25 postpaid.

RANDOM GLEANINGS FROM NATURE'S FIELDS—
By W. P. Pycraft, Asst. Cur. Zoological Dept., British Museum

CHARMING essays by a distinguished naturalist covering a wide and fascinating range of themes from cocoons to cats, owls to whales, pheasants to jelly fish, mermaids to horses; to appeal alike to lovers of the countryside, seashore, and garden. 90 illustrations, 206 pages, covering some 40 weekly articles which have appeared in the *Illustrated London News*.—$2.65 postpaid.

CHARLIE CHAN CARRIES ON—*By Earl D. Biggers*

ONE of the most unusual characters in this class of fiction is the Chinese detective whose Oriental philosophy appears constantly throughout the story to add an atmosphere of fatalism and keen observation. In our estimation no better stories of this kind have been written than the four that have come from the same pen. In sustained interest, amplitude of incidents, dramatic description, and careful writing, you will find this tale is hard to beat.—$2.15 postpaid.

FULL FATHOM FIVE—*By Frank H. Shaw*

THE story of five famous shipwrecks written by one who knows the sea intimately from the old windjammer days; he made four trips around the world starting as an apprentice before the mast. He has caught the tragedy, the stark reality of fatality, as well as the God-given heroism which has attended the majority of shipwrecks and made for itself a creed than which the annals of religion itself can find no better example. A fine group of authentic stories with 20 halftone page illustrations. But why, oh why the untidy, untrimmed edges in a book of such otherwise commendable format?—$3.20 postpaid.

KNOW THE FORD—*By Murray Fahnestock*

THIS is frankly a 96 page pamphlet giving the engineering points of excellence and comparison with other cars. It is an unusual presentation but extremely lucid and conclusive so that the layman in mechanics can easily acquire a thorough knowledge of the mechanisms, the reason for their design, and how they operate.—$2.10 postpaid.

CHEMICAL PATENT DEDICATED TO PUBLIC INVOLVED IN SUIT

A RECENT decision in a patent infringement suit brought by the Selden Company against the National Aniline and Chemical Company has attracted considerable interest in the chemical industry. Two patents were involved. The first patent covers a process for making phthalic anhydride, phthalic acid, benzoic acid, and naphthaquinones now used in a variety of industries—notably for the manufacture of dyes, medicinal products, plasticizers for nitrocellulose lacquers and artificial resins —and the second patent covers apparatus for carrying out the process, controlling the generating heat, and bringing about reactions of gases.

Both patents were granted without payment of statutory fees by the inventors under the act of March 3, 1883, which provides that any employee of the Government, other than of the Patent Office, may obtain a patent for an invention without payment of the fee required by law, provided that the inventor agrees that the patent when issued can be used by the Government or by anyone in the United States without payment of royalty.

When both inventions were conceived and perfected the patentees were employed as chemists in the United States Department of Agriculture and the evidence at the trial was clear that they considered they had dedicated their rights entirely to the public. However, before the patents had issued, they attempted to make an assignment to the Selden Company, who set up various defenses including some apparently conflicting decisions to justify their belief that they had a proper right under the patents and could prevent their infringement by others.

The court held, however, that the intention of the parties to dedicate their rights to the public was clear and that "the public" meant not only employees of the Government but the general public, and therefore the assignment to the Selden Company conveyed no rights, and everyone had an equal right to use the invention without payment to the inventors or any of their alleged assignees.—*A. E. B.*

UNUSED MARK DENIED REGISTRATION

IN *ex parte* Union Co-operative Insurance Association, First Assistant Commissioner Kinnan held that the Union Co-operative Insurance Association, of Washington, D.C., is not entitled to register, under the Act of 1905, as a trademark for printed books, pamphlets, circulars, and so forth, a mark consisting of the representation of a seal impressed in wax including concentric circles between which are written the words "Union Co-operative Insurance Association 1924" and within the inner circle the words "Union Life Insurance For Union Men, Their Families and Friends."

The ground of the decision is that there is no evidence presented that the matter above described was ever used as a trademark.

In his decision, after noting the statement of the examiner, that a large variety of specimens such as leaflets, post cards, and so forth, and a copy of a periodical entitled *Official Organ of the International Electrical Workers and Operators Published Monthly* had been filed; noting further that the alleged trademark appears on the inside of the cover of the periodical in connection with an advertisement of an insurance association and that this periodical contains general reading matter and many advertisements having nothing to do with insurance associations, the First Assistant Commissioner said:

"The various leaflets, post cards, and folders submitted as specimens are mere advertisements of insurance business, intermittently, irregularly, or sporadically issued and distributed indiscriminately without any thought of remuneration. The alleged mark is not, in consequence, used on these leaflets, post cards, and folders in connection with the sale of anything nor is it used in the journal as a name or device indicating the journal. The examiner has held that this use of the particular design is not a trademark use at all in connection with any of the specimens filed. His conclusion is deemed sound."

WHEAT PRODUCT TRADEMARKS

IN a recent decision, First Assistant Commissioner Kinnan held that the J. T. Fargason Grocer Company, of Memphis, Tennessee, is not entitled to register the term "Omega" as a trademark for macaroni, spaghetti, noodles, corn flakes, and rolled oats in view of the prior registration by the H. C. Cole Milling Company, of Chester, Illinois, of that term as a trademark for wheat flour and that the registration which the Fargason Company had obtained under the Act of 1905 should be cancelled.

The ground of the decision is that the goods of the parties are of the same descriptive properties and that the fact that the use by the Fargason Company was known to the officials of the Cole Company is no ground for refusing cancellation.

OLIVE OIL URGED AS MOTOR LUBRICANT

LUBRICATING oils and greases produced from olive oil in Spain are reported by Spanish experimenters to have shown satisfactory results in preliminary tests with motor vehicles and electric motors, according to a report from Consul Austin C. Brady at Malaga, made public by the Department of Commerce.

An appeal is being made to Spaniards to use the domestic product in place of imported mineral lubricants, imports of which are recorded at 64,022,232 pounds for 1928, a large share of which was supplied by the United States. Statistics of the Petroleum Monopoly place 1929 sales of mineral lubricants at 75,387,778 pounds.

PETITION FOR CANCELLATION DISMISSED

IN the case of the Texas Ichthyol Chemical Company *versus* Ichthyol-Gesellschaft, Cordes, Hermanni and Company, Cancellation No. 1085, First Assistant Commissioner Kinnan held that the petitioner for cancellation, the Texas Ichthyol Chemical Company (Texas Ammonium Ichthyolate Co., Substituted), of Burnet, Texas, was properly permitted to dismiss without prejudice its petition for cancellation.

In his decision the First Assistant Commissioner noted the arguments that had been presented and, after stating the appellant had set forth categorically the usual reasons that the federal courts have deemed persuasive in permitting, or refusing to permit, the plaintiff to dismiss the bill without prejudice, said:

"It may be said that none of the six reasons recited on page 12 of appellant's brief as having been relied upon by courts in denying similar motions is so far present in the case at bar as to justify the refusal of the petitioner's motion and the reversal of the decision of the examiner of interferences upon it. Clearly enough the appellant has sought no affirmative relief and nothing in the nature of a cross bill has been presented. It is not clear the appellant would be injured or prejudiced by the granting of the motion beyond the possible annoyance of renewed litigation.

"It is true such judgment would bar renewed proceedings of this character but the disposition of motions to discontinue has not, in equity proceedings, usually been influenced or determined by this consideration."

With reference to the argument that a question of public policy was involved and that the case was "ripe for decision" he said:

"It is not thought there is any public policy involved in the instant proceedings or, if there is any, it is too remote to be considered. As to the testimony being closed, the case being ready for final hearing, or, 'ripe for decision,' it is believed even if these matters are admitted to be true, they are not sufficient to bar the petitioner the grant of its motion to discontinue."

TOBACCO PIPE PRODUCTION LOWER

SMOKERS in the United States are forsaking the pipe, apparently, judging by production figures for last year, according to a statement Sept. 11 by the Assistant Chief Statistician of the Census of Manufactures, John F. Daly. The statement follows in full text:

That American smokers are forsaking the pipe, the historical, the original and probably the most leisurely manner of smoking, is indicated by census figures.

According to the preliminary census of manufacturers' statistics the production of tobacco pipes last year showed a decline of 25.1 percent as compared with the production in 1927. The total shipments or deliveries of tobacco pipes in 1929 by manufacturers in the United States were valued at 5,202,185 dollars, as against 6,946,576 dollars reported for 1927, the last preceding census year.

The pipe production in 1927 also represented a slight decline as compared with the 7,298,595 dollar total for 1925, and this in turn was materially lower than the 9,704,816 dollars reported for 1923.

Other figures on the industry for 1929 were also in keeping with those on production. Only 22 establishments were engaged primarily in the production of tobacco pipes last year, which number shows a decline of one as compared with 1927. The 22 manufacturers gave employment to 1667 wage earners, to whom they paid 1,994,057 dollars in wages, which represented decreases of 7.7 percent and 14.7 percent, respectively, as compared with 1807 wage earners and 2,278,537 dollars paid in wages in 1927.

For materials, containers, and electric current, the manufacturers paid 1,716,788 dollars, a decrease of 36.9 percent as compared with 2,722,706 dollars in 1927. The value added by manufacture (value of products, less cost of materials, and so forth) also showed a decline, being 3,751,898 dollars as against 4,551,100 dollars in 1927, a decrease of 17.6 percent.

Of the 5,202,185 dollars' worth of pipes produced last year, briar pipes totaled 4,530,464 dollars and corncob 556,031 dollars, while other pipes produced were valued at 115,690 dollars, and other products at 266,501 dollars.

DESCRIPTIVE MARKS DENIED

IN *ex parte* J. B. Martin Company, First Assistant Commissioner Kinnan held that the company is not entitled to register, under the Act of 1905, the word "Opalescent" as a trademark for silk velvets and velvets of silk and rayon, since this word is merely descriptive of the goods.

In his decision, after referring to the dictionary definition of the word "opalescent," the First Assistant Commissioner said:

"It is well known that the goods to which the applicant applies the notation, when considered as piece goods, are made in different colors and frequently possess the property of reflecting light at different angles with a kind of iridescence which, in some instances, may be fairly well termed 'opalescent.' The word is a common descriptive word in our language and any part of the public should be permitted to use it in connection with goods of this character and no one should be permitted its exclusive appropriation."

In another decision affecting the same company, Dr. Kinnan held that they are not entitled to register, under the Act of 1905, the term "Chinchilla" as a trademark for silk velvets and velvets made of silk and rayon, since the term also is merely descriptive of the goods.

In his decision, after noting that the examiner had relied upon certain decisions in support of his holding that the goods of the applicant are of the same descriptive properties as woolen piece goods or thick heavy cloth from which coats are frequently made, and noting applicant's argument that the name as defined in the dictionary is the name of a South American rodent or its fur and at the most would be merely descriptive of applicant's goods, the First Assistant Commissioner said:

"It is held, since this word has long been used to describe a fabric made somewhat in imitation of the fur of the animal, purchasers would be led to believe the applicant's goods were likewise made in imitation of the fur and would interpret the term as merely descriptive of the fabric. The term having been for so long a time applied to a fabric in a descriptive sense, it is deemed the applicant is properly held to be seeking registration of a mark which is merely descriptive of the character or quality of the goods."

RUBBER TIRES vs. RUBBER BELTING

FIRST Assistant Commissioner Kinnan recently held that the holding in a prior decision that C. Kenyon Company, Inc., of New York, New York, is not entitled to register a trademark for vehicle tires in view of a prior registration by the Goodyear Tire and Rubber Company of substantially the same mark upon belting, should be withdrawn in view of the registrant's statement that it had no objection to such registration and it was not deemed that there would be any confusion by the use of the mark on the different goods.

He further held that, since the refusal of registration had been made in the same decision in which the opposition to the registration had been dismissed, it was believed that, now that the mark was held registrable, the opposition should be reinstated to the extent that a new decision should be rendered which would give the opposer an opportunity to appeal if it so desired.

D. A. R. OPPOSES TRADEMARK

IN the case of National Society of the Daughters of the American Revolution *versus* T. Buettner and Company, Inc., First Assistant Commissioner Kinnan held that the latter is not entitled to register, as a trademark for fabrics upon which are stamped embroidery patterns, a mark consisting of the following notation, arranged as shown:

D
W E A V E
R

The ground of the decision is that the mark so suggests the name of the opposer as to be unregistrable.

In his decision he noted that the opposer organization is frequently referred to as "The D. A. R." and also noted the prohibition of the statute against the registration of names, and so forth, of any organization, and so forth, incorporated in any state and the provision of the Trademark Act that the word "states" includes the District of Columbia and that the opposer was incorporated in the District of Columbia.

He then said:

"In a proceeding where an opposer of this character is involved, public policy as well as the statute and the settled practice justifies waiving all doubts against the applicant. There appears to have been no satisfactory reason for making so prominent these letters "D A R" which it is a matter of common knowledge have come in substantially all parts of this country and among all classes to indicate the opposer society."

He then stated that irrespective of what might have been the applicant's intent: ". . . it is believed there is a probability of purchasers or customers attaching some significance to the use of these three letters and being misled into the belief that the opposer society indorsed or approved of the applicant's goods. Any such interpretation of the applicant's mark would damage the opposer since its name would be to that extent degraded to the level of commercial activities."

RUG ANCHORS

IT was recently held by First Assistant Commissioner Kinnan that The Hoover Company, of North Canton, Ohio, is not entitled to register the notation "Anchorug" as a trademark for a dressing to be applied to the back of a rug to prevent slipping and curling, in view of the prior adoption and use by the E. I. duPont de Nemours & Company, of Wilmington, Delaware, of the notation "Rug Anchor" as a trademark upon materials preventing rugs from slipping.

The ground of the decision is that the goods are of the same descriptive properties and the marks confusingly similar as applied thereto.

In his decision, after stating that the opposer had used the mark upon a sheet or mat, on one surface of which was placed an anti-slipping composition, the mat being adapted to be placed under a rug with the anti-slipping surface in engagement with the floor, while applicant's goods are in the nature of a liquid dressing to be applied to the rugs, and noting that the goods are physically unlike in appearance, the First Assistant Commissioner said:

"The goods of the parties would, clearly enough, not be confused by purchasers. They are, however, for the same general purpose of preventing by anti-slipping composition the slipping of the rug. In the one case the material is spread directly upon the rug and dries to a suitable consistency, while in the other case a similar composition as to function and purpose is spread upon the fabric, which in turn is made to engage the rug upon its other surface. It is deemed quite probable that anyone familiar with the opposer's goods, and seeing those of the applicant on the market, would be led to conclude the latter were produced by the opposer. That confusion of origin would result if the respective marks appeared in the same market upon the respective goods seems a fair conclusion."

With respect to the marks, he said:

"As to the marks themselves, that of the applicant is practically a mere reversal of the two words adopted by the opposer. There seems to be no reason why, if the applicant did not wish to obtain some advantage from opposer's commercial activities, the applicant selected a mark so nearly identical with that of the opposer."

INDEX TO VOLUME 143, JULY-DECEMBER, 1930

Lack of space makes it impossible to give many cross-references or to enter a given reference in more than one place. Each article is therefore entered where it is believed it will be most easily found. In every case, the general subject should be sought rather than the supposed specific title of an article. We call special attention to the classifications "Aviation," "Engineering," "Medicine," "Miscellaneous," etc., under which many items will be found, the location of which otherwise would be very puzzling.

CONSULTING RESEARCH LABORATORY

Complete equipment for Mechanical, Electrical, Radio and Optical work in our own fireproof building (over 6,000 square feet).

Experimental Models Made

SAMUEL O. HOFFMAN COMPANY
355 Hayes St. San Francisco

MAKE YOUR INVENTIONS PAY

Millions have been made from ideas properly developed and protected by inventors. One of the first steps is the development of a practical working model.

Send us rough sketch or model of your idea. We will submit complete report backed by 30 years' experience in model making. Confidential service. Modern equipment. Bank references furnished. FREE booklet "Making Inventions Pay."

CRESCENT TOOL COMPANY, Dept. H, Cincinnati, Ohio

METAL ARTICLES DEVELOPED

and manufactured. MODEL MAKING.
Reasonable prices and first class workmanship.
